Abstract

The beta transformation is the iterated map $\beta x \bmod 1$. The special case of $\beta = 2$ is known as the Bernoulli map, and is exactly solvable. The Bernoulli map provides a model for pure, unrestrained chaotic (ergodic) behavior: it is the full invariant shift on the Cantor space $\{0, 1\}^\omega$. The Cantor space consists of infinite strings of binary digits; it is notable for many properties, including that it can represent the real number line.

The beta transformation defines a subshift: iterated on the unit interval, it singles out a subspace of the Cantor space that is invariant under the action of the left-shift operator. That is, lopping off one bit at a time gives back the same subspace.

The beta transform seems to capture something basic about the multiplication of two real numbers: β and x . It offers insight into the nature of multiplication. Iterating on multiplication, one would get $\beta^n x$ – that is, exponentiation; the mod 1 of the beta transform distorts this in strange ways.

Analyzing the beta transform is difficult. The work presented here is more-or-less a research diary: a pastiche of observations and some shallow insights. One is that chaos seems to be rooted in how the carry bit behaves during multiplication. Another is that one can surgically insert “islands of stability” into chaotic (ergodic) systems, and have some fair amount of control over how those islands of stability behave. One can have islands with, or without a period-doubling “route to chaos”.

The eigenvalues of the transfer operator seem to lie on a circle of radius $1/\beta$ in the complex plane. Given that the transfer operator is purely real, the appearance of such a quasi-unitary spectrum unexpected. The spectrum appears to be the limit of a dense set of quasi-cyclotomic polynomials, the positive real roots of which include the Golden and silver ratios, the Pisot numbers, the n-bonacci (tribonacci, tetranacci, etc.) numbers.

1 Introduction

The last three or four decades of mathematical research has seen dramatic advances in the theory of subshifts. This text is mostly not about that, except to point out that

*Diary started in December 2017, with major updates published in February 2018 and December 2018.

this theory has very broad and important impact on many branches of physics and mathematics. From the perspective of the amateur enthusiast, the theory of subshifts finally exposes and makes clear some of the mysterious and intriguing behavior of fractals and of chaotic dynamical systems.

This text focuses almost entirely on just one particular map of the unit interval, the β -transform, defined as the iterated map $\beta x \bmod 1$. As such, it is an example of an iterated map on the unit interval of the real number line. Such maps have the form

$$f : [0, 1] \rightarrow [0, 1]$$

and the topic is the exploration of the consequence of iterating the map by composing:

$$f^n(x) = (f \circ f \circ \cdots \circ f)(x) = f(f(\cdots f(x) \cdots))$$

Such one-dimensional iterated maps have been heavily studied, and there is a large body of results, interconnecting many different concepts and results from mathematics, and so having a particularly broad range.

This text attempts to report some brand-new results on the β -transform. This is perhaps surprising, as one might think that the β -transform is sufficiently simple so as to be well-studied and well-understood, it being among the very simplest of iterated one-dimensional maps. This text also attempts to report these results in a naive and unsophisticated fashion, in the hope that this makes the text readable for the interested student and casual enthusiast.

Thus, although the author is personally excited by the advances in the field, this text is neither a survey of known results on the β -transform, nor does it much glance at most of the typical avenues that are available for studying one-dimensional maps. This text does focus extensively on the spectrum of the transfer operator (the “Ruelle Perron Frobenius operator”), and thus it contributes to the general “Koopmania”. Little prior knowledge is assumed, and the needed concepts are introduced in a very casual and informal way. This will, no doubt, completely discourage and dismay the formally trained mathematician. The best I can offer is to reiterate: “new results”, off the beaten track.

This text begins with some pretty pictures, showing the iterated tent and logistic maps, so as to remind the reader as to why this is an interesting problem to study. The fact is that the β -transformation is far more dry and abstract than the rather sexy logistic map, or its complex cousin, the Mandelbrot set. The hope is that the β -transformation is also simpler, and therefore, perhaps, easier to understand. The reader will soon discover that there is nothing particularly easy about it, and that, at every turn, one bumps into other interesting areas of mathematics that could, perhaps should shed some light, but don’t actually seem to do so, in practice.

The most fun for the casual reader might be chapter 5, on the periodic orbits, where the quasi-cyclotomic polynomials appear; these are polynomials of the form $p_n(z) = z^{k+1} - b_0 z^k - b_1 z^{k-1} - \cdots - b_{k-1} z - 1$ for the b_j being binary bits (zero or one). Also quite fun is the section on the islands of stability, which sheds light on how one can take a purely ergodic (chaotic) system, and surgically insert, as desired, islands of stability. The point here is that the classic logistic map attracted interest precisely because of its

interleaving of chaos and stability; it turns out, one can manufacture such systems, at will.

A word about the format of this paper: this is a *de facto* “research diary”, not a formal report. This, it contains various unfinished corners, maybe some errors, and notes-to-self.

1.1 Bernoulli shift

The Bernoulli shift (*aka* the bit-shift map, the dyadic transform or the full shift) is an iterated map on the unit interval, given by iteration of the function

$$b(x) = \begin{cases} 2x & \text{for } 0 \leq x < \frac{1}{2} \\ 2x - 1 & \text{for } \frac{1}{2} \leq x \leq 1 \end{cases} \quad (1)$$

The symbolic dynamics of this map gives the binary digit expansion of x . That is, write

$$b^n(x) = (b \circ b \circ \cdots \circ b)(x) = b(b(\cdots b(x) \cdots))$$

to denote the n -fold iteration of b and let $b^0(x) = x$. The symbolic dynamics is given by the bit-sequence

$$b_n(x) = \begin{cases} 0 & \text{if } 0 \leq b^n(x) < \frac{1}{2} \\ 1 & \text{if } \frac{1}{2} \leq b^n(x) \leq 1 \end{cases} \quad (2)$$

(Caution: n is a subscript on the left, and a superscript on the right! The left is a sequence, the right is an iteration. Using the letter b one both sides is a convenient abuse of notation.) Of course, the symbolic dynamics recreates the initial real number:

$$x = \sum_{n=0}^{\infty} b_n(x) 2^{-n-1} \quad (3)$$

All of this is just a fancy way of saying that a real number can be written in terms of its base-2 binary expansion. That is, the binary digits for x are the $b_n = b_n(x)$, so that

$$x = 0.b_0b_1b_2\cdots$$

The Bernoulli shift has many interesting properties, connecting it to the Cantor set and a large class of self-similar fractals. It is also connected to the modular group and elliptic functions (thence to number theory). It is also the primary example of an ergodic system, and, in a sense, has far-reaching implications for ergodic systems via Ornstein theory. These various connections are far too numerous to review here, beyond these brief mentions.

The current task is to attempt to see how many of these properties still hold in the more general case of the β -transformation.

1.2 Shift space

The use of the word “shift” here deserves a small bit of formality. A “shift space” can be formally defined to be a set of infinite sequences of a set of N letters (or symbols),

together with a shift operator T that takes each sequence, and lops off the left-most symbol. For the Bernoulli shift, there are $N = 2$ letters, taken from the set $\{0, 1\}$. For the Bernoulli shift, one is typically interested in the set of *all* possible infinite sequences: this is the “full shift”. One writes $\{0, 1\}^\omega$ for this shift space, ω denoting countable infinity. For the Bernoulli shift, the map $b(x)$ is the shift operator: it just lops off the left-most symbol.

In general, a shift space does not have to include every possible sequence of symbols; it does, however, by definition, have to be shift-invariant. That is, given some set S of infinite sequences of N symbols, the set S is a shift space if and only if, by lopping off the leading symbol of each string, one regains S again. In formulas, a shift space S must obey

$$TS = S$$

For example, $S = \{000\cdots, 111\cdots\}$ contains only two elements: the string of all zeros, and the string of all ones; lopping off the leading digit just returns S again. In general, shift spaces may contain a finite, or a countable, or an uncountable number of elements. In general, one defines the “full shift” as the space N^ω of all possible strings of N symbols. Subsets that are shift spaces are called “subshifts”.

The words “symbolic dynamics” also deserve some mention: given one specific sequence $x \in S$ out of the shift space S , one can ponder “where it goes to”, as one lops off a symbol at a time. This gives the “symbolic dynamics” or the “point dynamics” of the sequence. The “orbit” is defined as the set $\{T^m x \mid \text{integer } m \geq 0\}$ – that is, the set of all places that x goes to. There are several possibilities: one is that x is a fixed point, so that $Tx = x$. Another is that x is a repeating sequence of symbols, in which case iteration repeats as well: $T^m x = x$ holds whenever the repeat length is m ; this is a periodic orbit.

Most importantly, when there are non-periodic orbits, then there are uncountably many of them. That is, the number of periodic orbits is always countable: there are at most N starting points for an orbit, and they are of at most length m . This includes the “eventually periodic” orbits: those that begin with some finite initial sequence of “random” moves, eventually settling into a periodic recurrence. This cannot be done for the non-periodic orbits: they cannot be placed in lexicographic order; as the Cantor slash argument applies. The non-periodic orbits are always uncountable. In this sense, the non-periodic orbits are “more important”, in that they make up the bulk of all orbits. There are situations in which the periodic orbits can be said to “govern” the dynamics of the aperiodic ones; this is termed “coherent structure”. However such concepts are advanced, and are not obviously applicable to the current situation.

In what follows, the text will in general confine itself to the uncountable case. Periodic orbits exist, but will be ignored; in a certain strict sense, they constitute a set of measure zero. A number of glosses like this will be made: for example, the real numbers, and the Cantor space $\{0, 1\}^\omega$ are both uncountable; however, they are not in one-to-one correspondence, as some real numbers can have two different representations as bit sequences. Specifically, these are the fractions $(2n+1)/2^m$ for positive integers m, n – they can be validly represented by bit-sequences ending in all-zeros, or all-ones. There are countably many such fractions, termed the dyadic fractions. For the most part, this difference between the real number line, and the Cantor space will

be ignored.

1.3 Beta shift

The beta shift is similar to the Bernoulli shift, replacing the number 2 by a constant real-number value $1 < \beta \leq 2$. It can be defined as

$$T_\beta(x) = \begin{cases} \beta x & \text{for } 0 \leq x < \frac{1}{2} \\ \beta(x - \frac{1}{2}) & \text{for } \frac{1}{2} \leq x \leq 1 \end{cases} \quad (4)$$

This map, together with similar maps, is illustrated in figure 5 below.

Just as the Bernoulli shift generates a sequence of digits, so does the beta shift: write

$$k_n = \begin{cases} 0 & \text{if } 0 \leq T_\beta^n(x) < \frac{1}{2} \\ 1 & \text{if } \frac{1}{2} \leq T_\beta^n(x) \leq 1 \end{cases} \quad (5)$$

Given the symbolic dynamics, one can reconstruct the original value whenever $1 < \beta$ as

$$x = \frac{k_0}{2} + \frac{1}{\beta} \left(\frac{k_1}{2} + \frac{1}{\beta} \left(\frac{k_2}{2} + \frac{1}{\beta} \left(\frac{k_3}{2} + \frac{1}{\beta} (\dots) \right) \right) \right)$$

Written this way, the $T_\beta(x)$ clearly acts as a shift on this sequence:

$$T_\beta(x) = \frac{k_1}{2} + \frac{1}{\beta} \left(\frac{k_2}{2} + \frac{1}{\beta} \left(\frac{k_3}{2} + \frac{1}{\beta} \left(\frac{k_4}{2} + \frac{1}{\beta} (\dots) \right) \right) \right)$$

In this sense, this shift is “exactly solvable”: the above provides a closed-form solution for iterating and un-iterating the sequence.

Multiplying out the above sequence, one obtains the so-called “ β -expansion” of a real number x , namely the series

$$x = \frac{1}{2} \sum_{n=0}^{\infty} \frac{k_n}{\beta^n} \quad (6)$$

That is, the bit-sequence that was extracted by iteration can be used to reconstruct the original real number. Setting $\beta = 2$ in eqn 5 gives the Bernoulli shift. Explicitly, one has $T_2(x) = b(x)$.

Unlike the Bernoulli shift, not every possible bit-sequence occurs in this system. It is a subshift of the full shift: it is a subset of $\{0, 1\}^\omega$ that is invariant under the action of T_β . This is explored in greater detail in a later section.

1.4 Associated polynomial

The iterated shift can also be written as a finite sum. This is noted here; it will be useful in later sections. Observe that

$$T_\beta(x) = \beta \left(x - \frac{k_0}{2} \right)$$

and that

$$T_\beta^2(x) = \beta^2 x - \frac{\beta}{2} (\beta k_0 + k_1)$$

and that

$$T_\beta^3(x) = \beta^3 x - \frac{\beta}{2} (\beta^2 k_0 + \beta k_1 + k_2)$$

The general form is then:

$$T_\beta^p(x) = \beta^p x - \frac{\beta}{2} \sum_{m=0}^{p-1} k_m \beta^{p-m-1} \quad (7)$$

Since the k_m depend on both β and on x , this is not a “true” polynomial; however, it will be useful in analysis, later.

1.5 Density Visualizations

The “long-term dynamics” of the β -shift can be visualized by means of a “bifurcation diagram”. Scare quotes are used, as these are imprecise terms; greater precision will be provided shortly. The idea of a bifurcation diagram was made famous by the Feigenbaum map (shown in figure 4), and so the same idea is applied here: track orbits over long periods of time, and see where they go. This forms a density, which can be numerically explored by histogramming. This is shown in figure 2.

When this is done for the β -shift, one thing becomes immediately apparent: there are no actual “bifurcations”, no “islands of stability”, no period-doubling regions, none of the stuff normally associated with the Feigenbaum map. Although there are periodic orbits, these form a set of measure zero: the iteration produces purely chaotic motion for almost all values of x and all values of $\beta > 1$. In this sense, the beta transform provides a clean form of “pure chaos”,¹ without the pesky “islands of stability” popping up intermittently.

The visualization of the long-term dynamics is done by generating a histogram, and then taking the limit, as follows. One divides the unit interval into a fixed sequence of equal-sized bins; say a total of N bins, so that each is $1/N$ in width. Pick a starting x , and then iterate: if, at the n 'th iteration, one has that $j/N \leq b_\beta^n(x) < (j+1)/N$, then increment the count for the j 'th bin. After a total of M iterations, let $c(j; M)$ be the count in the j 'th bin. This count is the histogram. In the limit of a large number of iterations, as well as small bin sizes, one obtains a distribution:

$$\rho(y; x) = \lim_{N \rightarrow \infty} \lim_{M \rightarrow \infty} \frac{c(j; M)}{M} \text{ for } \frac{j}{N} \leq y < \frac{j+1}{N}$$

This distribution depends on the initial value x chosen for the point to be iterated; a “nice” distribution results when one averages over all starting points:

$$\rho(y) = \int_0^1 \rho(y; x) dx$$

¹Formal mathematics distinguishes between many different kinds of chaotic number sequences: those that are ergodic, those that are weakly or strongly Bernoulli, weakly or strongly mixing. The beta transform is known to be ergodic,[1] weakly mixing[2] and weakly Bernoulli.[3]

Numerically, this integration can be achieved by randomly sampling a large number of starting points. Observe, by definition, that $\rho(y)$ is a probability distribution:

$$1 = \int_0^1 \rho(x) dx$$

Probability distributions are the same thing as measures; they assign a density to each point on the unit interval. It can be shown that this particular distribution is invariant under iteration, and thus is often called the invariant measure, or sometimes the Haar measure.

For each fixed β , one obtains a distinct distribution $\rho_\beta(y)$. The figure 1 illustrates some of these distributions for a selection of fixed β . Note that, for $\beta < 1$, the distribution is given by $\rho_\beta(y) = \delta(y)$, a Dirac delta function, located at $y = 0$.

The general trend of the distributions, as a function of β , can be visualized with a Feigenbaum-style “bifurcation diagram”, shown in figure 2. This color-codes each distribution $\rho_\beta(y)$ and arranges them in a stack; a horizontal slice through the diagram corresponds to $\rho_\beta(y)$ for a fixed value of β .

1.6 Tent Map

The tent map is a closely related iterated map, given by iteration of the function

$$v_\beta(x) = \begin{cases} \beta x & \text{for } 0 \leq x < \frac{1}{2} \\ \beta(1-x) & \text{for } \frac{1}{2} \leq x \leq 1 \end{cases}$$

Its similar to the beta shift, except that the second arm is reflected backwards, forming a tent. The bifurcation diagram is shown in figure 3. Its is worth contemplating the similarities between this, and the corresponding beta shift diagram. Clearly, there are a number of shared features.

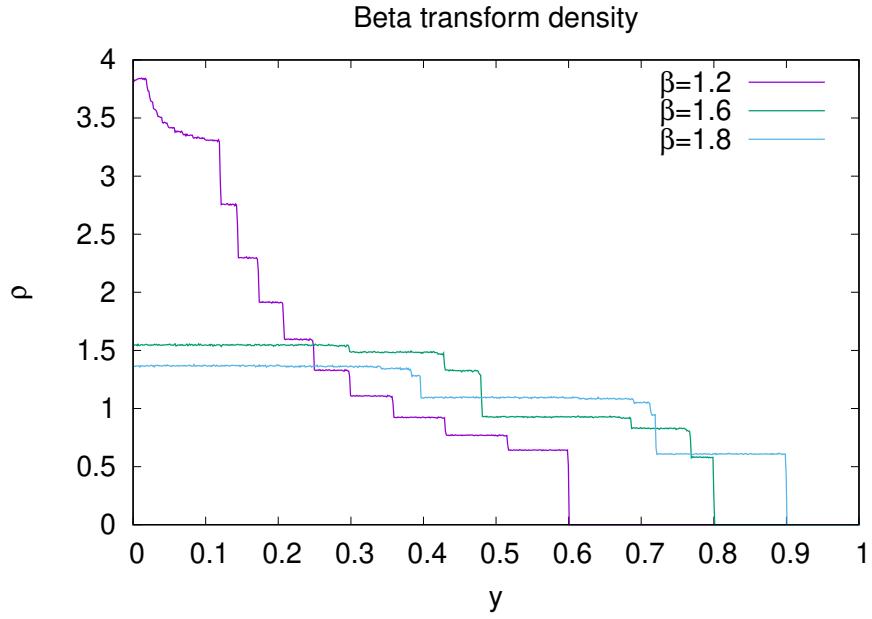

1.7 Logistic Map

The logistic map is related to the tent map, and is given by iteration of the function

$$f_\beta(x) = 2\beta x(1-x)$$

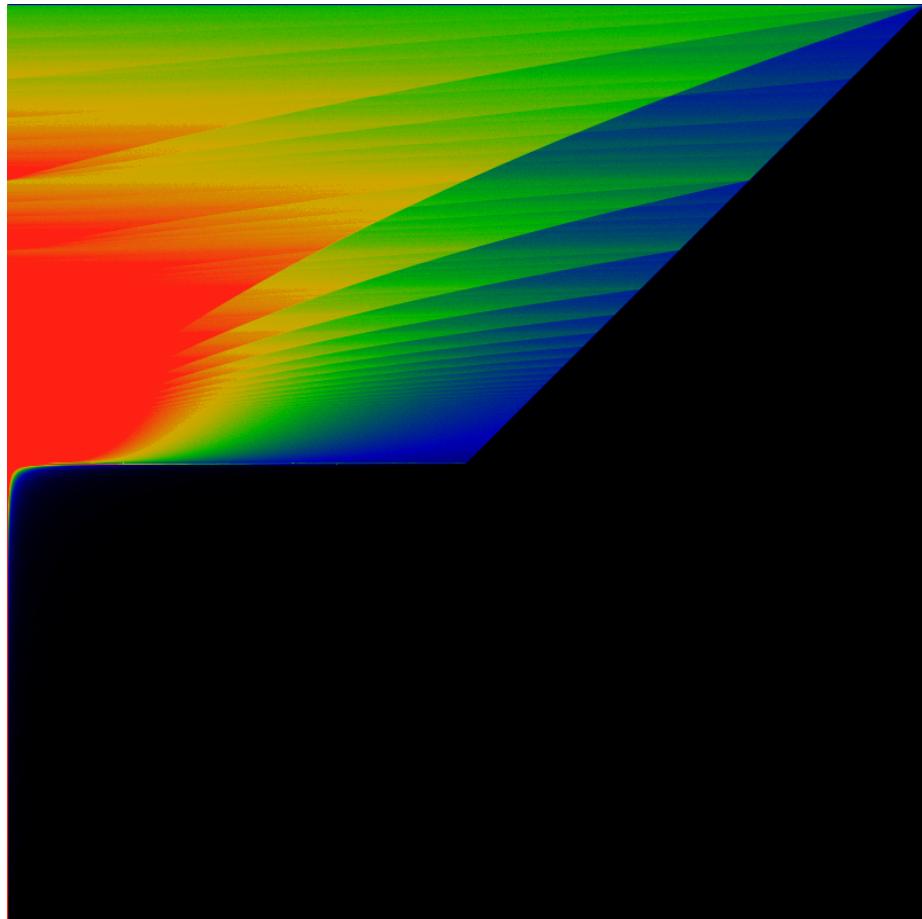

It essentially replaces the triangle forming the tent map with a parabola of the same height. That is, the function is defined here so that the the same value of β corresponds to the same height for all three maps. Although the heights of the iterators have been aligned so that they match, each exhibits rather dramatically different dynamics. The β -transform has a single fixed point for $\beta < 1$, and then explodes into a fully chaotic regime above that. By contrast, the logistic map maintains a single fixed point up to $\beta = 3/2$, where it famously starts a series of period-doubling bifurcations. The onset of chaos is where the bifurcations come to a limit, at $\beta = 3.56995/2 = 1.784975$. Within this chaotic region are “islands of stability”, which do not appear in either the β -transform, or in the tent map. The tent map does show a period-doubling regime, but in this region, there are no fixed points: rather, the motion is chaotic, but confined

Figure 1: Beta-shift Density Distribution

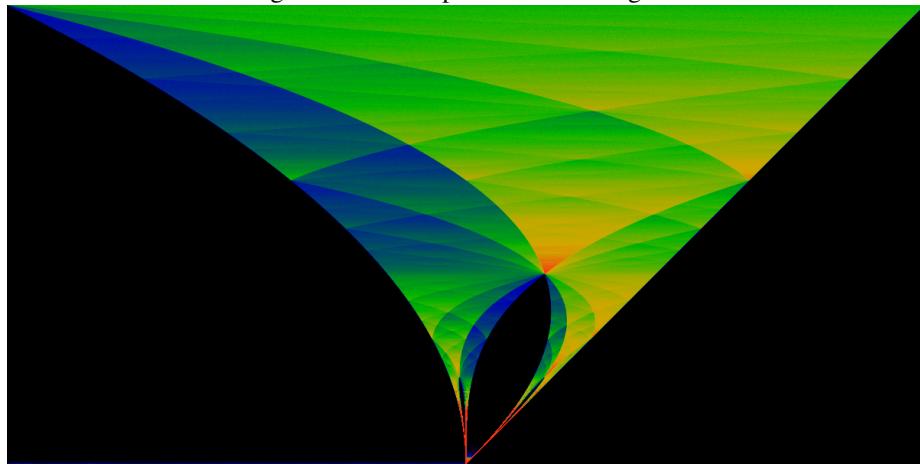

The above figure shows three different density distributions, for $\rho_{1.2}(y)$, $\rho_{1.6}(y)$ and $\rho_{1.8}(y)$, calculated numerically. These are obtained by histogramming a large number of point trajectories, as described in the text. The small quantities of jitter are due to a finite number of samples. To generate this figure, a total of $M = 4000$ iterations were performed, using randomly generated arbitrary-precision floats (using the Gnu GMP package), partitioned into $N = 800$ bins, and sampled 24000 times (or 30 times per bin) to perform the averaging integral. It will later be seen that the discontinuities in this graph occur at the ‘‘iterated midpoints’’ $m_p = T_\beta^p(\beta/2)$. The flat plateaus are not quite flat, but are filled with tiny steps. There is a discontinuous step at every p ; these are ergodically distributed, *i.e.* dense in the interval, so that there are steps everywhere.

Figure 2: Beta-shift Bifurcation Diagram

This figure shows the density $\rho_\beta(y)$, rendered in color. The constant β is varied from 0 at the bottom to 2 at the top; whereas y runs from 0 on the left to 1 on the right. Thus, a fixed value of β corresponds to a horizontal slice through the diagram. The color green represents values of $\rho_\beta(y) \approx 0.5$, while red represents $\rho_\beta(y) \gtrsim 1$ and blue-to-black represents $\rho_\beta(y) \lesssim 0.25$. The diagram is “interesting” only for $1 < \beta$; for smaller β ’s, one has that $\rho_\beta(y) = \delta(y)$, indicated by the column of red pixels on the left side of the image. The lines forming the fan shape are not actually straight, they only seem to be; in fact, they have a slight curve. This means that one cannot apply simple-minded guess-work to discover the overall diagram shown here.

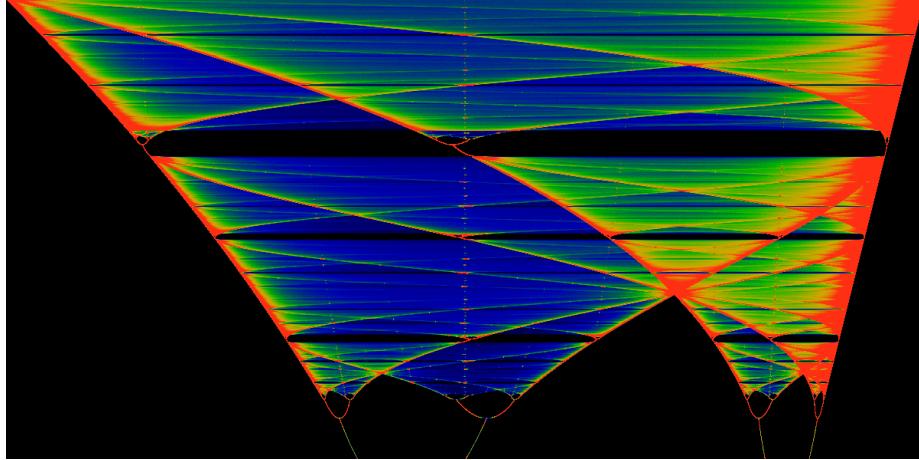

Figure 3: Tent Map Bifurcation Diagram

The bifurcation diagram for the tent map. The value of β runs from 1 at the bottom of the image, to 2 at the top. The color scheme is adjusted so that green represents the average value of the distribution, red represents areas of more than double the average value, while blue shows those values that are about half the average value. Note that this is a different color scheme than that used in figure 2; that scheme would obliterate the lower half of this figure in red.

The black areas represent parts of the iterated range that are visited at most a finite number of times. To the right, the straight boundary line indicates that after one iteration, points in the domain $\beta/2 \leq x \leq 1$ are never visited. To the left, points in the domain $0 \leq x \leq \beta(1 - \beta/2)$ are never visited more than a finite number of times.

Figure 4: Logistic Map Bifurcation Diagram

The logistic map bifurcation diagram. The value of β runs from 1.75 at the bottom of the image, to 2 at the top. The color scheme is adjusted so that green represents the average value of the distribution, red represents areas of more than double the average value, while blue shows those values that are about half the average value. Clearly, the orbits of the iterated points spend much of their time near the edges of the diagram. This is a very widely reproduced diagram. The goal here is not to waste space reproducing it yet again, but to draw attention to the similarities between this diagram, and the corresponding diagram for the beta shift.

to multiple arms. At any rate, the period doubling occurs at different values of β than for the logistic map.

The bifurcation diagram is shown in figure 4. Again, it is worth closely examining the similarities between this, and the corresponding tent-map diagram, as well as the β -transform diagram. Naively, it would seem that the general structure of the chaotic regions are shared by all three maps. Thus, in order to understand chaos in the logistic map, it is perhaps easier to study it in the β -transform.

The general visual similarity between the figures 2, 3 and 4 should be apparent, and one can pick out and find visually similar regions among these three illustrations. Formalizing this similarity is a bit harder, but it can be done: there is a way to make all three of these maps be “topologically conjugate” to one-another. This is perhaps surprising to some readers, but is based on the observation that the “islands of stability” in the logistic map are countable, and are in one-to-one correspondence with certain “trouble points” in the iterated beta transformation. These are in turn in one-to-one correspondence with rational numbers. With a slight distortion of the beta transformation, the “trouble points” can be mapped to the islands of stability, in essentially the same way that “phase locking regions” or “Arnold tongues” appear in the circle map. But this is all for a later section, again, mentioned here only to whet the appetite.

1.8 Beta Transformation

After exactly one iteration of the beta shift, all initial points $\beta/2 \leq x \leq 1$ are swept up into the domain $0 \leq x < \beta/2$, and never leave. Likewise, the range of the iterated beta-shift is $0 \leq x < \beta/2$. Thus, an alternative representation of the beta shift, filling the entire unit square, can be obtained by dividing both the domain and range by $\beta/2$ to obtain the function

$$t_\beta(u) = \begin{cases} \beta u & \text{for } 0 \leq u < \frac{1}{\beta} \\ \beta u - 1 & \text{for } \frac{1}{\beta} \leq u \leq 1 \end{cases} \quad (8)$$

This can be written more compactly as $t_\beta(x) = \beta x \bmod 1$. In this form, the function is known as the beta-transform, and is often called the β -transformation, presenting a typesetting challenge to search engines when used in titles of papers. The orbit of a point x in the beta-shift is identical to the orbit of a point $u = 2x/\beta$ in the beta-transformation. Explicitly comparing to the beta-shift of eqn 4:

$$T_\beta^n(x) = \frac{\beta}{2} t_\beta^n\left(\frac{2x}{\beta}\right) \quad (9)$$

The beta-shift and the β -transformation are essentially “the same function”; this text works almost exclusively with the beta-shift, and is thus idiosyncratic, as it flouts the more common convention of working with the β -transformation. The primary reason for doing this is to retain contact with the β -shift being a subshift of the full shift.

After a single iteration of the tent map, a similar situation applies. After one iteration, all initial points $\beta/2 \leq x \leq 1$ are swept up into the domain $0 \leq x < \beta/2$. After a finite number of iterations, all points $0 < x \leq \beta(1 - \beta/2)$ are swept up, so that the remaining iteration takes place on the domain $\beta(1 - \beta/2) < x < \beta/2$. It is worth defining a “sidetent” function, which corresponds to the that part of the tent map in which iteration is confined. It is nothing more than a rescaling of the tent map, ignoring those parts outside of the above domain that “wander away”. The sidetent is given by

$$s_\beta(u) = \begin{cases} \beta(u-1) + 2 & \text{for } 0 \leq u < \frac{\beta-1}{\beta} \\ \beta(1-u) & \text{for } \frac{\beta-1}{\beta} \leq u \leq 1 \end{cases}$$

Performing a left-right flip on the side-tent brings it closer in form to the beta-transformation. The flipped version, replacing $u \rightarrow 1 - u$ is

$$f_\beta(u) = \begin{cases} \beta u & \text{for } 0 \leq u < \frac{1}{\beta} \\ 2 - \beta u & \text{for } \frac{1}{\beta} \leq u \leq 1 \end{cases}$$

The tent map (and the flipped tent) exhibits fixed points (periodic orbits; mode-locking) for the smaller values of β . These can be eliminated by shifting part of the tent downwards, so that the diagonal is never intersected. This suggests the “sidetarp”:

$$a_\beta(u) = \begin{cases} \beta u & \text{for } 0 \leq u < \frac{1}{\beta} \\ \beta(1-u) & \text{for } \frac{1}{\beta} \leq u \leq 1 \end{cases}$$

The six different maps under consideration here are depicted in figure 5. It is interesting to compare three of the bifurcation diagrams, side-by-side. These are shown in figure 6.

1.9 Dynamical Systems

A brief review of dynamical systems is in order, as it provides a coherent language with which to talk about and think about the beta-shift. The technical reason for this is that a subshift $S \subset \{0, 1\}^\omega$ provides a more natural setting for the theory, and that a lot of the confusion about what happens on the unit interval is intimately entangled with the homomorphism 3 (or 6 as the case may be). Disentangling the subshift from the homomorphism provides a clearer insight into what phenomena are due to which component.

The review of dynamical systems here is more-or-less textbook-standard material; it is included here only to provide a firm grounding for later discussion.

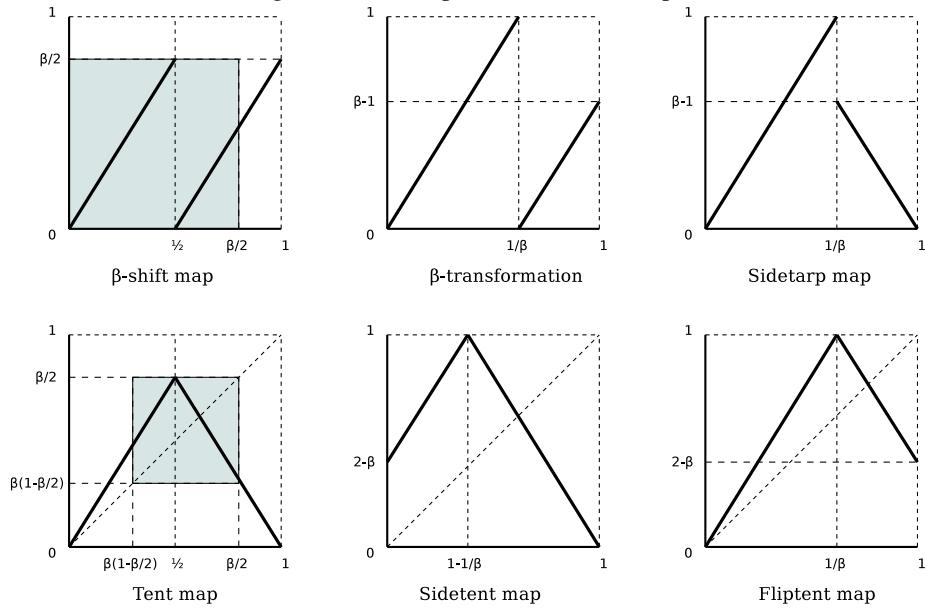

The Cantor space $\{0, 1\}^\omega$ can be given a topology, the product topology. The open sets of this topology are called “cylinder sets”. These are the infinite strings in three symbols: a finite number of 0 and 1 symbols, and an infinite number of * symbols, the latter meaning “don’t care”. Set union is defined location-by-location, with $0 \cup * = 1 \cup * = *$ and set intersection as $0 \cap * = 0$ and $1 \cap * = 1$. Set complement exchanges 0 and 1 and leaves * alone: $\bar{0} = 1$, $\bar{1} = 0$ and $\bar{*} = *$. The topology is then the collection of all cylinder sets. Note that the intersection of any finite number of cylinder sets is still a cylinder set, as is the union of an infinite number of them. The product topology does *not* contain any “points”: strings consisting solely of just 0 and 1 are *not* allowed in the topology. By definition, topologies only allow finite intersections, and thus don’t provide any way of constructing “points”. Of course, points can always be added “by hand”, but doing so tends to generate a topology (the “box topology”) that is “too fine”; in particular, the common-sense notions of a continuous function are ruined by fine topologies. The product topology is “coarse”.

The Borel algebra, or sigma-algebra, takes the topology and also allows set complement. This effectively changes nothing, as the open sets are still the cylinder sets, although now they are “clopen”, as they are both closed and open.

Denote the Borel algebra by \mathcal{B} . A shift is now a map $T : \mathcal{B} \rightarrow \mathcal{B}$ that lops off the leading symbol of a given cylinder set. This provides strong theoretical advantages over working with “point dynamics”: confusions about counting points and orbits and defining densities go away. This is done by recasting discussion in terms of functions $f : \mathcal{B} \rightarrow \mathbb{R}$ from Borel sets to the reals (or the complex numbers \mathbb{C} or other fields, when this is interesting). An important class of such functions are the measures. These are functions $\mu : \mathcal{B} \rightarrow \mathbb{R}$ that are positive, and are “compatible” with the sigma algebra, in that $\mu(A \cup B) = \mu(A) + \mu(B)$ whenever $A \cap B = \emptyset$ and (for product-space measures) that $\mu(A \cap B) = \mu(A)\mu(B)$ for all $A, B \in \mathcal{B}$. The measure of the total space $\Omega = \{0, 1\}^\omega$ is by convention unity: $\mu(\Omega) = 1$.

The prototypical example of a measure is the Bernoulli measure, which assigns probability p to any string containing a single 0 and the rest all *’s. By complement, a string containing a single 1 and the rest all *’s has probability $1 - p$. The rest follows from the sigma algebra: a cylinder set consisting of m zeros and n ones has measure

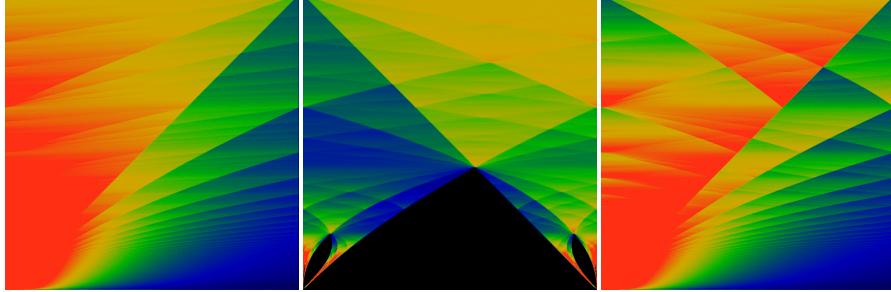

Figure 5: Iterated piece-wise linear maps

The beta shift map, shown in the upper left, generates orbits that spend all of their time in the shaded area: a box of size $\frac{\beta}{2} \times \frac{\beta}{2}$. Enlarging this box to the unit square gives the β -transformation. The tent map resembles the beta shift, except that one arm is flipped to make a tent-shape. After a finite number of iterations, orbits move entirely in the shaded region; enlarging this region to be the unit square gives the sidetent map. Flipping it left-right gives the fliptent map. Although it is not trivially obvious, the fliptent map and the sidetent map have the same orbits, and thus the same bifurcation diagram.

The bottom three maps all have fixed points and periodic orbits, essentially because the diagonal intersects the map. The top three maps have no periodic orbits, and are purely chaotic, essentially because the diagonal does not intersect them. Note that the slopes and the geometric proportions of all six maps are identical; they are merely rearrangements of the same basic elements.

Figure 6: Beta transform and Side-tent

The left figure shows the bifurcation diagram for the β -transform, as it is normally defined as the $\beta x \bmod 1$ map. It is the same map as the beta shift, just rescaled to occupy the entire unit square. In all other respects, it is identical to 2.

The middle figure is a similarly-rescaled tent map, given the name “side tent” in the main text. It is essentially identical to 3, with the middle parts expanded and the sides removed. In both figures, β runs from 1 at the bottom to 2 at the top. The right-hand-side figure is the “sidetarp”, clearly its an oddly-folded variant of the beta transform.

$p^m(1-p)^n$. It is usually convenient to take $p = 1/2$, the “fair coin”; the Bernoulli process is a sequence of coin tosses.

The map given in equation 3 is a homomorphism from the Cantor space to the unit interval. It extends naturally to a map from the Borel algebra \mathcal{B} to the algebra of intervals on the unit interval. It is not an isomorphism: cylinder sets are both open and closed, whereas intervals on the real number line are either open, or closed (or half-open). It is convenient to take the map as a map to closed intervals, so that it’s a surjection onto the reals, although usually, this detail does not matter. What does matter is if one takes $p = 1/2$, then the Bernoulli measure is preserved: it is mapped onto the conventional measure on the real-number line. Thus, the cylinder set $0***\dots$ is mapped to the interval $[0, 1/2]$ and $1***\dots$ is mapped to $[1/2, 1]$ and both have a measure of $1/2$ and this extends likewise to all intersections and unions. Points have a measure of zero. That is, the homomorphism 3 preserves the fair-coin Bernoulli measure.

Although the map of eqn 3 is not an isomorphism, it is more-or-less safe for most practical purposes to treat it as such. For any closed interval, there is a unique corresponding cylinder set. The only trouble arises at a countable number of points: all dyadic rationals have two expansions, not one, and so there, the map is not invertible. However, the points all have a measure of zero in both cases, and there are only a countable number of such points, and the mapping always takes points to points. Thus, the inverse exists for almost all members of the algebra and is unique whenever an interval has positive measure.

Much of what is said above still holds for subshifts. Recall, a subshift S is a subspace $S \subset \{0, 1\}^\omega$ that is invariant under the shift T , so that $TS = S$. The space S

inherits a topology from $\{0, 1\}^\omega$; this is the subspace topology. The Borel algebra \mathcal{B} is similarly defined, as are measures. One can now (finally!) give a precise definition for an invariant measure: it is a measure μ such that $\mu \circ T^{-1} = \mu$, or more precisely, for which $\mu(T^{-1}(\sigma)) = \mu(\sigma)$ for almost all cylinder sets $\sigma \in S$. This is what shift invariance looks like. Note carefully that T^{-1} and not T is used in the definition. This is because T^{-1} is a surjection while T is not: every cylinder set σ in the subshift “came from somewhere”; we want to define invariance for all σ and not just for some of them.

The T^{-1} is technically called a “pushforward”, and it defines a linear operator \mathcal{L}_T on the space \mathcal{F} of all functions $f : \mathcal{B} \rightarrow \mathbb{R}$. It is defined as $\mathcal{L}_T : \mathcal{F} \rightarrow \mathcal{F}$ by setting $\mathcal{L}_T : f \mapsto f \circ T^{-1}$. It is obviously linear, in that $\mathcal{L}_T(af + bg) = a\mathcal{L}_T(f) + b\mathcal{L}_T(g)$. This pushforward is canonically called the “transfer operator” or the “Ruelle-Frobenius-Perron operator”. Like any linear operator, it has a spectrum. The precise spectrum depends on the space \mathcal{F} .

The canonical example is again the Bernoulli shift. For this, we invoke the inverse of the mapping of eqn 3 so that $f : [0, 1] \rightarrow \mathbb{R}$ is a function defined on the unit interval, instead of $f : \mathcal{B} \rightarrow \mathbb{R}$. When \mathcal{F} is the space of real-analytic functions on the unit interval, that is, the closure of the space of all polynomials in $x \in [0, 1]$, then the spectrum of \mathcal{L}_T is discrete. It consists of the Bernoulli polynomials $B_n(x)$ corresponding to an eigenvalue of 2^{-n} . That is, $\mathcal{L}_T B_n = 2^{-n} B_n$. Note that $B_0(x) = 1$ is the invariant measure on the full shift. For the space of square-integrable functions $f : [0, 1] \rightarrow \mathbb{R}$, the spectrum of \mathcal{L}_T is continuous, and consists of the unit disk in the complex plane; the corresponding eigenfunctions are fractal. Even more interesting constructions are possible; the Minkowski question mark function provides an example of a measure on $\{0, 1\}^\omega$ that is invariant under the shift defined by the Gauss map $h(x) \mapsto \frac{1}{x} - \lfloor \frac{1}{x} \rfloor$. That is, as a measure, it solves $\mathcal{L}_T ?' = ?'$ with $?$ the Minkowski question mark function, and $?'$ its derivative; note that the derivative is “continuous nowhere”. This rather confusing idea (of something being “continuous nowhere”) can be completely dispelled by observing that it is well-defined on all cylinder sets in \mathcal{B} and is finite on all of them – not only finite, but less than one, as any good measure must obey.

These last examples are mentioned so as to reinforce the idea that working with \mathcal{B} instead of the unit interval $[0, 1]$ really does offer some strong conceptual advantages. They also reinforce the idea that the Bernoulli shift is not the only “full shift”. In the following text, we will be working with subshifts, primarily the beta-shift, but will draw on ideas from the above so as to make rigorous statements about measureability and invariance, without having to descend into either *ad hoc* hand-waving or provide painfully difficult (and confusing) reasoning about subsets of the real-number line.

1.10 Beta Transformation Literature Review and References

The β -transformation, in the form of $t_\beta(x) = \beta x \bmod 1$ has been well-studied over the decades. The beta-expansion 5 was introduced by A. Renyi[1], who demonstrates the existence of the invariant measure. The ergodic properties of the transform were proven by W. Parry[2], who also shows that the system is weakly mixing.

An explicit expression for the invariant measure was independently obtained by

A.O. Gel'fond[4] and by W. Parry[2], as a summation of step functions

$$v_\beta(y) = \frac{1}{F} \sum_{n=0}^{\infty} \frac{\varepsilon_n(y)}{\beta^n} \quad (10)$$

where ε_n is the digit sequence

$$\varepsilon_n(y) = \begin{cases} 0 & \text{if } t_\beta^n(1) \leq y \\ 1 & \text{otherwise} \end{cases}$$

and F is a normalization constant. By integrating $\varepsilon_n(y)$ under the sum, the normalization is given by

$$F = \sum_{n=0}^{\infty} \frac{t_\beta^n(1)}{\beta^n}$$

In the same way that a dyadic rational $p/2^n$ has two different binary expansions, one ending in all-zeros, and a second ending in all-ones, so one may also ask if and when a real number x might have more than one β -expansion (for fixed β). In general, it can; N. Sidorov shows that almost every number has a continuum of such expansions![5]

Conversely, the “univocal numbers” are those values of β for which there is only one, unique expansion for $x = 1$. These are studied by De Vries.[6]

The β -transformation has been shown to have the same ergodicity properties as the Bernoulli shift.[3] The fact that the beta shift, and its subshifts are all ergodic is established by Climenhaga and Thompson.[7]

An alternative to the notion of ergodicity is the notion of universality: a β -expansion is universal if, for any given finite string of bits, that finite string occurs somewhere in the expansion. This variant of universality was introduced by Erdős and Komornik[8]. Its is shown by N. Sidorov that almost every β -expansion is universal.[9] Conversely, there are some values of β for which rational numbers have purely periodic β -expansions;[10] all such numbers are Pisot numbers.[11]

The symbolic dynamics of the beta-transformation was analyzed by F. Blanchard[12]. A characterization of the periodic points are given by Bruno Maia[13]. A discussion of various open problems with respect to the beta expansion is given by Akiyama.[14]

When the beta expansion is expanded to the entire real-number line, one effectively has a representation of reals in a non-integer base. One may ask about arithmetic properties, such as the behavior of addition and multiplication, in this base - for example, the sum or product of two β -integers may have a fractional part! Bounds on the lengths of these fractional parts, and related topics, are explored by multiple authors.[15, 16, 17]

Certain values of β - generally, the Pisot numbers, generate fractal tilings,[18, 19, 20, 10, 14] which are generalizations of the Rauzy fractal. An overview, with common terminology and definitions is provided by Akiyama.[21] The tilings, sometimes called (generalized) Rauzy fractals, can be thought of as living in a direct product of Euclidean and p -adic spaces.[22]

The set of finite beta-expansions constitutes a language, in the formal sense of model theory and computer science. This language is recursive (that is, decidable by a Turing machine), if and only if β is a computable real number.[23]

The zeta function, and a lap-counting function, are given by Lagarias[24]. The Hausdorff dimension, the topological entropy and general notions of topological pressure arising from conditional variational principles is given by Daniel Thompson[25]. A proper background on this topic is given by Barreira and Saussol[26].

None of the topics or results cited above are made use of, or further expanded on, or even touched on below. That's mostly because what follows below is just a ... different perspective on the topic. Not intentionally so; it just happened to come out that way.

2 Symbolic Dynamics

A brief review of the Cantor set is in order.

The Bernoulli shift corresponds to the sequence of binary digits of a real number. Such sequences can be imagined to belong to the space of all possible sequences of binary digits, the Cartesian product of infinitely many copies of the set containing two elements:

$$\{0, 1\} \times \{0, 1\} \times \{0, 1\} \times \cdots = \{0, 1\}^\omega = 2^\omega$$

This set is the Cantor set. It has a natural topology, the product topology, whose open sets are finite lengths of digits, possibly interspersed with some “don’t care” markers (“don’t care” meaning “either 0 or 1”), and terminated by an infinite tail of “don’t care” markers. Equation 3 provides a homomorphism from the Cantor set to the unit interval. There are other homomorphisms into a broad variety of fractals. Essentially all of the strange phenomena of fractals and of iterated functions follows from the product topology on this sequence.

The self-similarity of many kinds of fractals can be described with the Cantor set. This arises from the self-similarity of the product space under the action of a shift: specifically, the left-shift, which discards the left-most digit, and shifts the rest over by one. The shift operator itself is that operator that performs this shift; self-similar fractals can be seen to be eigenstates of the shift operator.

The infinitely-deep binary tree is another manifestation of the Cantor set. The set $\{0, 1\}$ of the product space can be interpreted as the set $\{L, R\}$ of left-right moves. At each point in a binary sequence, one can make a choice of one of two things: to move left or right. This naturally suggests a binary decision tree.

A byproduct is the presence of some implicit, ambient hyperbolic space. The infinite binary tree, when drawn on flat two-dimensional space, simply “runs out of room”, as each subsequent branching pushes closer together. The infinite binary tree can be embedded in the simplest hyperbolic space, the Poincaré disk or upper-half-plane, in such a way that the distance, the spacing between two neighboring nodes is always the same. Visually, this takes the form of some prototypical M.C. Escher drawing, of a repeated fractal form moving out to the edge of a disk. This makes the self-similar shape of the infinite binary tree manifest: as one moves from one location to another, one always sees “the same thing” in all directions: the space is homogeneous.

The rational numbers play a very special role in the infinite binary tree. Dyadic rationals, of the form $(2p+1)/2^n$ for integers p and n correspond to bit sequences (eqn 2) that terminate in all-zeros after a finite number of moves. That is, after an

initial “chaotic” sequence, they settle down to a fixed point of period one. General rational numbers p/q behave similarly, in that after an initial “chaotic” sequence, they settle down to periodic orbits of some fixed period. The bit-sequence becomes cyclic. This cyclic behavior implies that most of classical number theory can be dragged into the proceedings. Any particular statement that classical number theory makes with regard to rational numbers, or even modular forms, can be promptly ported over to a statement about the bit-sequences and the orbits of the Bernoulli shift, usually taking on a strange and unrecognizable form.

All of these things go together, like hand in glove: whenever one is manifest and visible, the others are lurking right nearby, in the unseen directions. All of these things can be given a formal and precise definition, and their explicit inter-relationships articulated. This has been done by a wide variety of authors over the last four decades; a proper bibliography would be overwhelming. I have written extensively on all of these topics, trying to present them in the simplest, most jargon-free way that I can, in a dozen different texts available wherever you found this one. The ideas will not be repeated here; they are not immediately useful to the current proceedings. None-the-less, the general interplay between all of these concepts is extremely important to understand, and bubbles constantly under the surface of the current proceedings. In essence, shifts and subshifts are interesting precisely because they touch on so many different topics; and, conversely, so many different areas of mathematics can inform the subshift.

2.1 Symbolic Dynamics

Given that iteration can generate strings of binary digits, and that these can be reassembled back into real numbers, it is interesting to ask what those mappings look like. To firm up the notation, let $B = (b_n) = (b_0, b_1, \dots)$ denote a sequence of bits (or symbols) and write

$$x_\beta(B) = \frac{1}{2} \sum_{n=0}^{\infty} \frac{b_n}{\beta^n} \quad (11)$$

as the real number generated from that sequence. Conversely, given a real number x , let $K_\beta(x) = (k_{n;\beta}(x))$ denote the sequence of bits obtained by iterating the beta shift on x with constant β ; that is, the sequence generated by eqn. 5. The bit sequence for $K_2(x)$ is just the bit sequence $(b_n(x))$ generated by eqn 2. The transformations between symbol sequences and real numbers make sense only when $1 < \beta \leq 2$.

Two interesting functions can be considered. One is the compressor

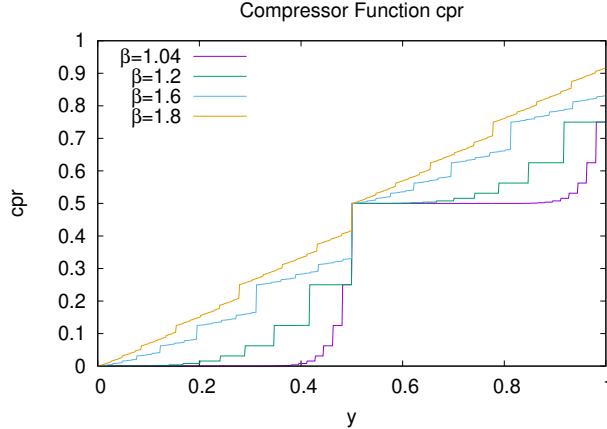

$$\text{cpr}_\beta(y) = x_2(K_\beta(y))$$

and the other is the expander

$$\text{pdr}_\beta(y) = x_\beta(K_2(y)) \quad (12)$$

The terms “compressor” and “expander” are being invented here to indicate negative and positive Lyapunov exponents associated with the two functions. For almost all y , the compressor function is pushing nearby points closer together; the total measure of

Figure 7: Compressor Function

This illustrates the compressor function for various values of β . As should be clear, almost all input values are mapped to a set of discrete output values.

the range of the compressor function is less than one. Likewise, for almost all y , the expander function is pushing nearby points apart. These two functions are illustrated in figures 7 and 8.

The two functions are adjoint; specifically, one has that $\text{pdr}_\beta(\text{cpr}_\beta(y)) = y$ for almost all y but that $\text{cpr}_\beta(\text{pdr}_\beta(y)) \neq y$. The former relation is equivalent to eqn. 6. Not all possible sequences of bit strings appear in the beta shift sequence $K_\beta(x)$; that is, this function is not a surjection onto $\{0, 1\}^\omega$. This manifests itself as the gaps in the range of the compressor function, clearly visible in figure 7. If a sequence of bits is viewed as a sequence of left-right moves walking down a binary tree, this implies that some branches of the tree are never taken, and can be pruned. Only branches on the right are ever pruned: That is, there can be arbitrarily long sequences of zeros in the expansion, but the longest possible sequence of 1's is always bounded. The longest run of 1's possible is the largest value of n that satisfies

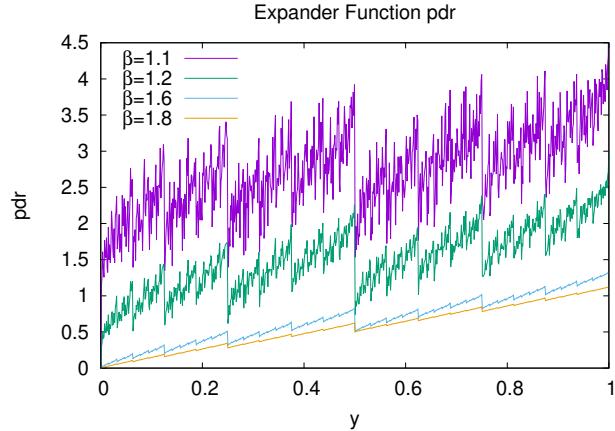

$$2 \geq \frac{1 + \beta + \beta^2 + \dots + \beta^{n-1}}{\beta^{n-1}}$$

Solving, the bound is

$$n = 1 + \left\lfloor \frac{-\log(2 - \beta)}{\log \beta} \right\rfloor \quad (13)$$

That is, every n 'th right branch is pruned from the binary tree. For example, a run of three 1's in a row is possible only for $\beta \geq (1 + \sqrt{5})/2 = 1.618034\dots$ the Golden Ratio. The range of $\text{cpr}_\beta(y)$ is most of, but not all of the Cantor set. The figure 9 visualizes the range of the compressor as a function of β .

Figure 8: Expander Function

This illustrates the expander function for various values of β . As should be clear, almost all neighboring input values are mapped to wildly different output values.

2.2 Shifts with holes

Viewed as a shift space, as opposed to a cut-down binary tree, the trimming can be thought of as a punching of holes into the full shift. This requires a bit of mental gymnastics. Let (a, c) be an (open) interval on the real number line: $(a, c) = \{x \mid a < x < c\}$. Given the Bernoulli shift $b(x) = T_2(x)$ from eqns 1 or 4, consider the set

$$\mathcal{I}(a, c) = \{x \mid b^n(x) \notin (a, c) \text{ for any } n \geq 0\}$$

That is, as one iterates on some fixed x , one requests that no iterate $b^n(x)$ ever lands in the interval (a, c) . In essence, one has punched a hole in the unit interval; this corresponds to a ‘‘hole’’ in the full Bernoulli shift. The set $\mathcal{I}(a, c)$ is what remains after punching such a hole.

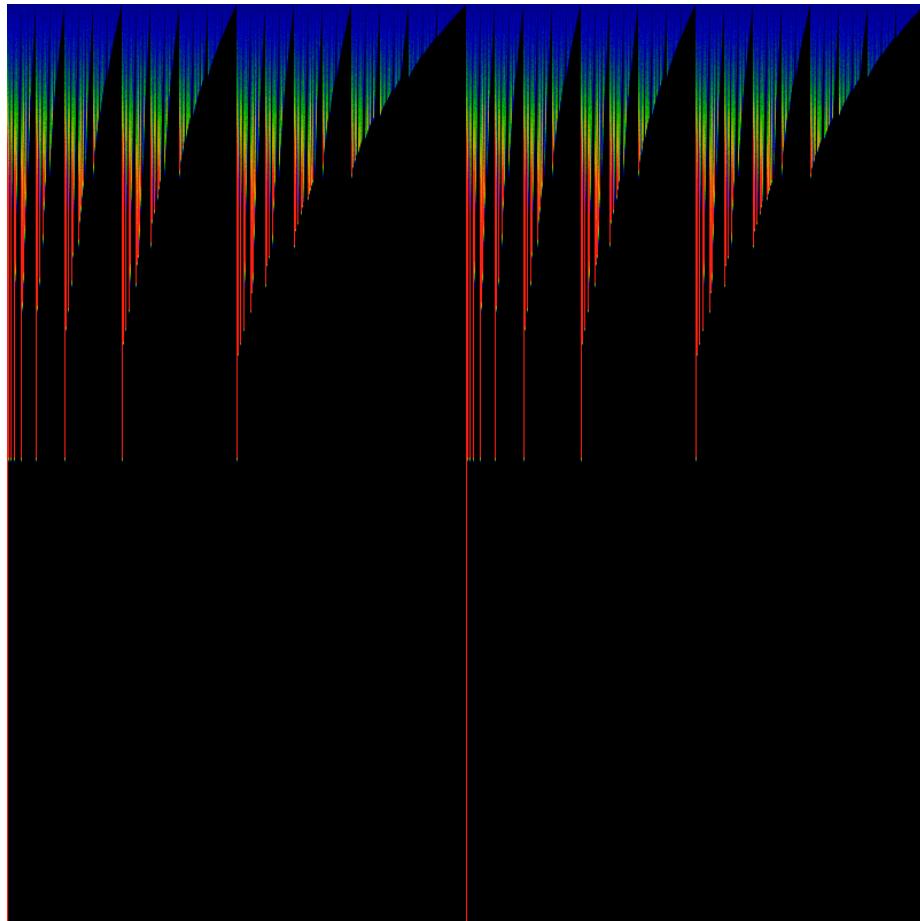

How can this be visualized? Considering the case $n = 0$, its clear that $\mathcal{I}(a, c)$ cannot contain (a, c) . That is, $\mathcal{I}(a, c) \cap (a, c) = \emptyset$. For $n = 1$, the interval (a, c) can come from one of two places: either from $(\frac{a}{2}, \frac{c}{2})$ or from $(\frac{a+1}{2}, \frac{c+1}{2})$, and so neither of these can be in $\mathcal{I}(a, c)$. Continuing, for $n = 2$, the intervals $(\frac{a}{4}, \frac{c}{4})$, $(\frac{a+1}{4}, \frac{c+1}{4})$, $(\frac{a+2}{4}, \frac{c+2}{4})$ and $(\frac{a+3}{4}, \frac{c+3}{4})$ must also be gone. Continuing in this fashion, one proceeds with an infinite hole-punch: to obtain $\mathcal{I}(a, c)$, one just cuts out (a, c) and everything that iterates to (a, c) . For the holes, write

$$\mathcal{H}(a, c) = \bigcup_{n=0}^{\infty} \bigcup_{k=0}^{2^n-1} \left(\frac{a+k}{2^n}, \frac{c+k}{2^n} \right)$$

and for the interval with the holes punched out:

$$\mathcal{I}(a, c) = [0, 1] \setminus \mathcal{H}(a, c)$$

Figure 9: Range of the compressor

This figure illustrates a color coded visualization of the range of the compressor function. As before β varies from 0 at the bottom to 2 at the top, and y varies from 0 on the left to 1 on the right. In general, the compressor function maps intervals of the real number line to single points; the color corresponds to the size (the measure) of the intervals that were mapped to that particular point. Blue corresponds to a compression of the measure by about 1, green to a compression of about 2-3, and yellow-red to a compression greater than that.

where \cup denotes set-union and \setminus denotes set subtraction. It is not hard to see that, in the end, this forms a contorted Cantor set, using the standard midpoint-subtraction algorithm, but with different endpoints. The canonical Cantor set is built by taking $(a, c) = (\frac{1}{3}, \frac{2}{3})$.

Note that both $\mathcal{H}(a, c)$ and $\mathcal{I}(a, c)$ are subshifts: applying the left-shift to them just returns the same set again. Both are invariant under the action of the shift operator. In formulas,

$$b\mathcal{H}(a, c) = \mathcal{H}(a, c)$$

and

$$b\mathcal{I}(a, c) = \mathcal{I}(a, c)$$

where, for notational simplicity, the parenthesis are not written, so that for the set S , write $bS = b(S)$. As shifts, it's more appropriate to view both as sets of bit-sequences, so that the proper relationship between one and the other should have been written as

$$\mathcal{I}(a, c) = \{0, 1\}^\omega \setminus \mathcal{H}(a, c)$$

How should these subshifts be visualized as strings? Let $(b_n(x))$ be the bit sequence generated by x , for some $a < x < c$. The cut operation states that such strings can never occur anywhere in $\mathcal{I}(a, c)$. Explicitly, $\mathcal{I}(a, c)$ never contains sequences of the form $d_0d_1d_2 \cdots d_k b_0(x) b_1(x) b_2(x) \cdots$ for any arbitrary leading bits $d_0d_1d_2 \cdots d_k$.

How should these subshifts be visualized as binary trees? The simplest case to visualize is to take $a = m/2^n$ and $c = (m+1)/2^n$ being dyadic rationals, for some integers m, n . In this case, one takes the bit-expansion for both have the same n leading bits: one starts at the root of the tree, and walks down the binary tree, making left-right moves in accordance with this sequence, and after n moves, arrives at a node above a subtree. Just cut out this subtree, in its entirety. That's the first cut. Now repeat the process, for the left and right subtrees, from off the root, *ad infinitum*. For a and c not dyadic rationals, the process is more complicated. If a and c are ordinary rationals, thus having a repeating bit-sequence, one performs in the same way, but cyclically walking down the side branches of subtrees. For a and c irrational, the algorithm is considerably more complicated, and is left as an exercise for the reader :-).

A general classification of shifts with holes, for the beta transform, was performed by Lyndsey Clark[27].

2.3 Generalized compressors and expanders

The range of the compressor function is a shift with a hole. Specifically, for a given β , the range of cpr_β is $\mathcal{I}\left(\frac{\beta}{2}, \frac{1}{2}\right)$. The construction for shifts with holes can then be applied to construct generalized compressor and expander functions. One way, which is really rather cheesy, but it works, is to define the function

$$\text{dcpr}_{\beta, \gamma}(a; x) = \sum_{n=0}^{\infty} \left[\frac{1}{\gamma^{n+1}} \sum_{k=0}^{2^n-1} \delta\left(x - \frac{a+k}{\beta^n}\right) \right]$$

and then define the generalized compressor as

$$\text{cpr}(a; x) = \int_0^x \text{dcpr}(a; y) dy$$

That is, as one walks along the unit interval, from left to right, one picks up points with weights on them, obtaining a generalized Devil's staircase (Cantor-Vitali) function. This generalization does not seem to be terribly useful here, and is left to rot.

2.4 Self-similarity

Subshifts are, by definition, self-similar. If S is a subshift, and T is the shift operator, then $TS = S$ is the key relation obeyed by a subshift. It is fun to see how this actually manifests itself on the unit interval.

So, the two functions cpr and pdr are self-similar. The pdr function demonstrates classic period doubling self-similarity: namely, under $g(x) = x/2$, it behaves as

$$(\text{pdr}_\beta \circ g)(x) = \text{pdr}_\beta\left(\frac{x}{2}\right) = \frac{1}{\beta} \text{pdr}_\beta(x)$$

while under reflection $r(x) = 1 - x$, it behaves as

$$(\text{pdr}_\beta \circ r)(x) = \text{pdr}_\beta(1 - x) = \frac{\beta}{2(\beta - 1)} - \text{pdr}_\beta(x)$$

Note that

$$\lim_{x \rightarrow 1} \text{pdr}_\beta(x) = \frac{\beta}{2(\beta - 1)}$$

The full dyadic monoid is generated by the generators g and r . It consists of all finite-length strings of the form

$$\gamma = g^{a_1} r g^{a_2} r g^{a_3} r \cdots r g^{a_m}$$

for a finite-length list of positive integers $(a_1, a_2, a_3, \dots, a_m)$. Note that this list can be interpreted as a continued fraction; this establishes an isomorphism between the continued fractions and the dyadic monoid. This isomorphism is conventionally called the Minkowski question-mark function. We can be a bit more explicit. Write

$$g_\beta(x) = \frac{x}{\beta}$$

and

$$r_\beta(x) = \frac{\beta}{2(\beta - 1)} - x$$

Note that $r_\beta \circ r_\beta = 1$ so that it is a reflection, and that $r_2(x) = 1 - x$ is the reflection of the unit interval. For strings of binary digits, the reflection performs the exchange of $0 \leftrightarrow 1$; its a mirroring symmetry. The above relationships then become

$$g_\beta \circ \text{pdr}_\beta = \text{pdr}_\beta \circ g_2$$

and

$$r_\beta \circ \text{pdr}_\beta = \text{pdr}_\beta \circ r_2$$

The symmetry under the dyadic monoid is simply the statement that

$$\gamma_\beta \circ \text{pdr}_\beta = \text{pdr}_\beta \circ \gamma_2$$

for any γ of the above form.

The function cpr also exhibits self-similarity, although it alters (expands) what happens on the x axis. Several self-similarities are apparent. First, for $0 \leq x \leq 1$, one has

$$\text{cpr}_\beta\left(\frac{x}{2}\right) = \frac{1}{2} \text{cpr}_\beta\left(\frac{\beta x}{2}\right)$$

Equivalently, for $0 \leq y \leq \beta/2$ one can trivially restate the above as

$$\text{cpr}_\beta\left(\frac{y}{\beta}\right) = \frac{1}{2} \text{cpr}_\beta(y) \quad (14)$$

Although this follows trivially, this restatement helps avoid certain confusions later in this text. This can also be written as

$$g_2 \circ \text{cpr}_\beta = \text{cpr}_\beta \circ g_\beta$$

There is obviously no corresponding reflection symmetry. The left and right halves are identical to one-another, but offset:

$$\text{cpr}_\beta\left(\frac{1}{2} + \frac{x}{2}\right) = \frac{1}{2} + \text{cpr}_\beta\left(\frac{x}{2}\right)$$

It follows that

$$\text{cpr}_\beta\left(\frac{1}{2} + \frac{y}{\beta}\right) = \frac{1}{2} + \frac{1}{2} \text{cpr}_\beta(y)$$

Combining the above results into one, one has that

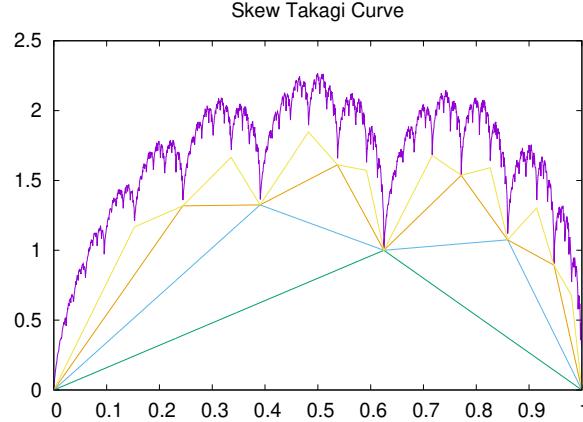

$$\text{cpr}_\beta\left(\frac{y}{\beta}\right) + \text{cpr}_\beta\left(\frac{1}{2} + \frac{y}{\beta}\right) = \frac{1}{2} + \text{cpr}_\beta(y)$$

This last form is interesting, as it makes an appearance in relation to the transfer operator, defined below.

2.5 Other things with similar symmetry

The cpr curve is just one that belongs to a class of such curves. As an example, one may construct a Takagi (blancmange) curve by iterating triangles whose peak is located at $1/\beta$. The Takagi curve is an example of a curve transforming under a 3-dimensional representation of the dyadic monoid; the cpr curves transforms under a two-dimensional representation. See my paper on the Takagi curve for details. Figure

Figure 10: Skew Takagi Curve

This figure shows a skew Takagi curve, and the first four steps of its construction. The initial triangle is of height 1; the apex is located at $1/\beta$, for $\beta = 1.6$ in this figure. Subsequent triangles obtain a height of $w=0.7$ above the apex point, and are similarly skew.

10 shows such a curve. Denote by $\text{tak}_{\beta,w}(x)$ a curve constructed in this fashion. The transformation properties of this curve include self-similarity on the left, as

$$\text{tak}_{\beta,w}\left(\frac{x}{\beta}\right) = x + w \text{tak}_{\beta,w}(x)$$

for $0 \leq x \leq 1$ and self-similarity on the right, as

$$\text{tak}_{\beta,w}\left(\frac{1}{\beta} + x\left(1 - \frac{1}{\beta}\right)\right) = 1 - x + w \text{tak}_{\beta,w}(x)$$

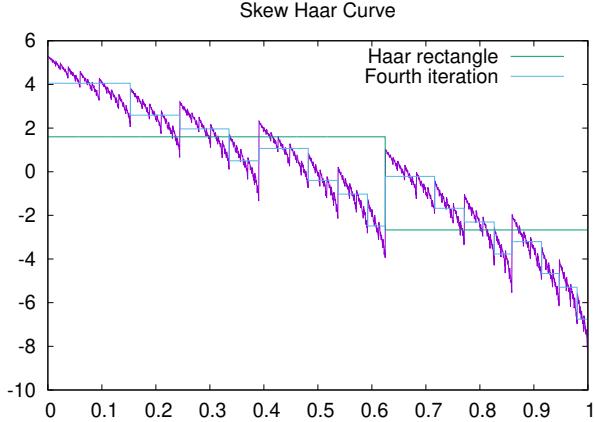

Both of these properties follow directly from the construction of the curve; they can be taken as the defining equations for the curve. That is, the curve can be taken as that function which satisfies these two recursion relations.

The derivative of the skew Takagi curve is shown in figure 11, and, for lack of a better name, could be called the skew Haar fractal wavelet. It can be defined as the formal derivative

$$\text{har}_{\beta,w}(x) = \frac{d}{dx} \text{tak}_{\beta,w}(x)$$

This formal derivative is well-defined, as the skew Takagi is smooth and piecewise-linear almost everywhere; the places where it has corners is a dense set of measure zero. That is, the derivative is defined everywhere, except on a set of measure zero, which happens to be dense in the unit interval.

Figure 11: Skew Haar Wavelet

This figure shows the derivative of the skew Takagi curve. Note that it is piece-wise constant everywhere. The mother wavelet is shown, as well as the fourth iteration. The specific values graphed are $\beta = 1.6$ and $w = 0.7$.

Note that the Haar fractal wavelet is piece-wise constant everywhere. It is constructed from a “mother wavelet” given by

$$h_\beta(x) = \begin{cases} \beta & \text{for } 0 \leq x < \frac{1}{\beta} \\ \frac{-\beta}{\beta-1} & \text{for } \frac{1}{\beta} \leq x \leq 1 \end{cases} \quad (15)$$

which is then iterated on to form the fractal curve $\text{har}_{\beta;w}(x)$. The self symmetries are

$$\text{har}_{\beta;w}\left(\frac{x}{\beta}\right) = \beta + w \text{har}_{\beta;w}(x)$$

and

$$\text{har}_{\beta;w}\left(\frac{1}{\beta} + x\left(1 - \frac{1}{\beta}\right)\right) = -\frac{\beta}{\beta-1} + w \text{har}_{\beta;w}(x)$$

2.6 Fixed Points; Periodic Orbits

The Bernoulli shift, given by eqn 2, generates every possible bit-sequence. As was observed in a previous section, not every possible bit-sequence occurs in the beta shift. The longest sequence of all-ones possible was given by eqn 13. Arbitrary finite lengths of zeros do appear; but are there fixed points, i.e. sequences that terminate in all-zeros? Clearly, $x = 1/2\beta^n$ is such a fixed point: after $n+1$ iterations of eqn 4, x goes to zero, and stays there. Is this the only such fixed point? The answer depends on β . If β can be written in the form of $\beta^n = 2m+1$ for some integers n and m , then the values of x which can iterate down to zero in $n+1$ steps are dense in the interval $[0, \beta/2]$.

Curiously, such values β are dense in the interval $[1, 2)$. A later chapter performs explores periodic orbits in great detail.

3 Transfer operators

The discovery and study of invariant measures, as well as of decaying states can be approached via the transfer operator, or, properly named, the Ruelle-Frobenius-Perron operator. This is an operator that captures the behavior of a distribution under the action of a map. The invariant measure is an eigenstate of this operator; indeed, it provides a formal definition for what it means to be invariant under the action of the map. The general theory for this was reviewed in section 1.9 We recap the defintion of the transfer operator in it's more limited sense, as a linear operator acting in a point-wise fashion, on the space of functions on the unit interval of the real number line. In the general setting, it is a pushforward. In the more limited setting, this pushforward nature of the map is a bit obscured.

Given an iterated map $g : [0, 1] \rightarrow [0, 1]$ on the unit interval, the transfer operator defines how distributions are acted on by this map. It is defined as

$$[\mathcal{L}_g f](y) = \sum_{x=g^{-1}(y)} \frac{f(x)}{|g'(x)|}$$

The left adjoint of the transfer operator is the composition operator (Koopman operator). This is defined as

$$[\mathcal{C}_g f](y) = f(g(y))$$

The Koopman operator is adjoint, in the sense that $\mathcal{L}_g \mathcal{C}_g = 1$ but that, in general, $\mathcal{C}_g \mathcal{L}_g \neq 1$.

3.1 The β -shift Transfer Operator

The transfer operator for the β -shift and the β -transform are only superficially different. We'll give both of them here, as it is sometimes useful to reference one or the other, depending on the situation. Superficially, they seem to have a different form, but are in the end just scaled versions of one-another. The transfer operator the beta-shift map $T_\beta(x)$ is

$$[\mathcal{L}_\beta f](y) = \begin{cases} \frac{1}{\beta} \left[f\left(\frac{y}{\beta}\right) + f\left(\frac{y}{\beta} + \frac{1}{2}\right) \right] & \text{for } 0 \leq y \leq \beta/2 \\ 0 & \text{for } \beta/2 < y \leq 1 \end{cases}$$

or, written more compactly

$$[\mathcal{L}_\beta f](y) = \frac{1}{\beta} \left[f\left(\frac{y}{\beta}\right) + f\left(\frac{y}{\beta} + \frac{1}{2}\right) \right] \Theta\left(\frac{\beta}{2} - y\right) \quad (16)$$

where Θ is the Heaviside step function. The transfer operator for the beta-transform map $t_\beta(x)$ is

$$[\mathcal{M}_\beta f](y) = \frac{1}{\beta} \left[f\left(\frac{y}{\beta}\right) + f\left(\frac{y}{\beta} + \frac{1}{\beta}\right) \Theta(\beta - 1 - y) \right]$$

The density distributions graphed in figure 1 are those functions satisfying

$$[\mathcal{L}_\beta \rho](y) = \rho(y) \quad (17)$$

That is, the $\rho(y)$ satisfies

$$\rho(y) = \frac{1}{\beta} \left[\rho\left(\frac{y}{\beta}\right) + \rho\left(\frac{y}{\beta} + \frac{1}{2}\right) \right] \Theta\left(\frac{\beta}{2} - y\right) \quad (18)$$

Likewise, the Gelfond-Parry measure of eqn 10 satisfies

$$[\mathcal{M}_\beta v_\beta](y) = v_\beta(y)$$

Recall that $\rho(y) = \frac{2}{\beta} v_\beta\left(\frac{2y}{\beta}\right) \Theta\left(\frac{\beta}{2} - y\right)$; the two invariant measures are just scaled copies of one-another. Both are normalized so that $\int_0^1 \rho(y) dy = \int_0^1 v_\beta(y) dy = 1$.

Both of these invariant measures are the Ruelle-Frobenius-Perron (RFP) eigenfunctions of the corresponding operators, as they correspond to the largest eigenvalues of the transfer operators, in each case being the eigenvalue one.

More generally, one is interested in characterizing the eigenspectrum

$$[\mathcal{L}_\beta \rho](y) = \lambda \rho(y)$$

for eigenvalues $|\lambda| \leq 1$ and eigenfunctions $\rho(y)$. Solving this equation requires choosing a space of functions in which to work. Natural choices include any of the Banach spaces, and in particular, the space of square-integrable functions. Particularly interesting is the space of almost-smooth functions, those having discontinuities at only a countable number of locations, but otherwise being infinitely differentiable. Although the discussion so far implicitly conditions one to restrict oneself to real-valued functions, and to consider only real-valued eigenvalues, this is perhaps too sharp a restriction. It will become clear in the following chapters that even the most basic form of \mathcal{L}_β has a complex-valued spectrum. At any rate, it should be obvious that, whatever the choice of function space, one must have that $\rho(y) = 0$ whenever $\beta < 2y$. This turns out to be a rather harsh condition.

At least one basic fact is known: for at least some kinds of function spaces, the RFP eigenfunction is given by Gel'fond and Parry, as shown in eqn 10. More precisely, it is just the rescaled form $\rho(x) = v(2x/\beta)$ for $x < \beta/2$ and zero otherwise. Changing vocabulary, this is sometimes called the “invariant measure”; as it describes a measure on the unit interval. That is, for the space of all possible measures on the unit interval, the Gel'fond-Parry measure is one of the eigenfunctions of the transfer operator. Some caution is advised here: for the special case of $\beta = 2$, that is, the Bernoulli shift, one has as an eigenfunction the Minkowski measure[28]; it has eigenvalue 1, but is otherwise quite pathological: it is continuous nowhere, zero on the rationals, and divergent on the rest (i.e. on a “fat” Cantor set). There's no particular reason to think that this holds only for $\beta = 2$; measures can be, in general, very unusual functions.

A very minor simplification can be achieved with a change of variable. Let $y = \frac{\beta}{2} - \varepsilon$. Then the eigenequation becomes

$$\lambda \beta \rho\left(\frac{\beta}{2} - \varepsilon\right) = \rho\left(\frac{1}{2} - \frac{\varepsilon}{\beta}\right) + \rho\left(1 - \frac{\varepsilon}{\beta}\right)$$

The second term vanishes whenever $\beta/2 < 1 - \varepsilon/\beta$ or $\varepsilon < \beta(1 - \beta/2)$ and so one has the simpler recurrence relation

$$\lambda \rho(y) = \frac{1}{\beta} \rho\left(\frac{y}{\beta}\right) \quad (19)$$

whenever $\beta(\beta - 1) < 2y \leq \beta$.

The equations 18 and 19 can be treated as recurrence relations, defining the $\lambda = 1$ eigenstate. Recursing on these gives exactly the densities shown in figure 1. Computationally, these are much, much cheaper to compute, at least for β much larger than 1, although convergence issues present themselves as β approaches 1. The resulting density may be called the Ruelle-Frobenius-Perron eigenstate; because it can be quickly computed ignoring this, there's another "little" problem: all of the diagonal entries are larger than one. Such solutions would describe not the decaying eigenfunctions, but the exploding ones. Instead, it provides an alternative view of figure 1, free of stochastic sampling noise.

3.2 (No) Real-analytic solutions

What happens if we start with the assumption that there might be a real-analytic solution to the eigen-equation? It is reasonable to expect that this hope is doomed, but the process is instructive anyway. Start by positing

$$f(y) = \sum_{n=0}^{\infty} a_n y^n$$

Ignoring, for a moment, the step function, and plugging this into the above gives

$$\frac{1}{\beta} \left[f\left(\frac{y}{\beta}\right) + f\left(\frac{y}{\beta} + \frac{1}{2}\right) \right] = \sum_{m=0}^{\infty} \frac{y^m}{\beta^{m+1}} \left[a_m + \sum_{j=0}^{\infty} \binom{m+j}{m} 2^{-j} a_{m+j} \right]$$

Matching, term by term, this gives the eigenequation $\lambda a_m = \sum_k L_{mk} a_k$ with L_{mk} an upper-triangular matrix, having matrix entries

$$L_{mk} = \frac{1}{\beta^{m+1}} \left[1 + \frac{1}{2^{k-m}} \binom{k}{m} \right]$$

for $k \geq m$ and $L_{mk} = 0$ otherwise. Although this is upper-triangular, and thus solvable, the omission of the step function was critical: the eigenfunction has to vanish for $y > \beta/2$ and there is no way to do this with a real-analytic function. Inserting a step function into the mix ruins the term-by-term comparison. That is, positing

$$f(y) = \Theta\left(\frac{\beta}{2} - y\right) \sum_{n=0}^{\infty} a_n y^n$$

prevents the term-by-term comparison from passing through.

Perhaps working with the beta-shift here is a bad idea. Let's try again with the beta-transform. Without ignoring the step function, and plugging through as before gives:

$$\frac{1}{\beta} \left[f\left(\frac{y}{\beta}\right) + f\left(\frac{y}{\beta} + \frac{1}{\beta}\right) \Theta(\beta - 1 - y) \right] = \sum_{m=0}^{\infty} \frac{y^m}{\beta^{m+1}} \left[a_m + \sum_{j=0}^{\infty} \binom{m+j}{m} \beta^{-j} a_{m+j} \Theta(\beta - 1 - y) \right]$$

The step function prevents term-by-term comparison. If it is conveniently ignored or forgotten, then a pseudo-solution is easy: the term-by-term solution gives the eigenequation $\lambda a_m = \sum_k M_{mk} a_k$ with M_{mk} an upper-triangular matrix, having matrix entries

$$M_{mk} = \frac{1}{\beta^{m+1}} \left[1 + \frac{1}{\beta^{k-m}} \binom{k}{m} \right]$$

for $k \geq m$ and $M_{mk} = 0$ otherwise. This matrix is solvable. Its solutions are effectively the Bernoulli polynomials. By ignoring the step function, all that has happened is that we've re-discovered the real-analytic solutions to the Bernoulli process; indeed, the term-by-term comparison does work for the special case of $\beta = 2$, when the step function really does disappear.

3.3 Almost-solutions

If one ignores the Heaviside step function in the definition 16, one easily finds a number of “almost solutions” to the transfer operator. These are most easily discussed by defining the operator

$$[\mathcal{P}_\beta f](y) = \frac{1}{\beta} \left[f\left(\frac{y}{\beta}\right) + f\left(\frac{y}{\beta} + \frac{1}{2}\right) \right]$$

Solving this operator is relatively straight-forward. Consider, for example, the monomial $f(y) = y^n$. Clearly, $[\mathcal{P}_\beta y^n]$ is a polynomial of degree n and that therefore, the space of polynomials is closed under the action of \mathcal{P}_β . But this result is even stronger: the monomials provide a basis in which \mathcal{P}_β is upper-triangular, *i.e.* solvable. Its eigensolutions in this basis are polynomials. The eigenspectrum is clearly discrete, and is given by $(\beta)^{-n-1}$ for integers n corresponding to the degree of the polynomial eigensolution.

This all goes horribly wrong if one instead considers \mathcal{L}_β and the almost-monomials $f(y) = y^n \Theta\left(\frac{\beta}{2} - y\right)$. This does not provide a basis that is closed under the action of \mathcal{L}_β . Attempting to find the closure by iterating on \mathcal{L}_β generates a splatter of step functions. This case is examined more closely in the next chapter.

Attempting some guess-work, the self-similarity of the cpr function suggests an opening. Specifically, let $\text{ei}_\beta(x) = \text{cpr}_\beta(x) - 1/2$. The one finds that

$$\begin{aligned} [\mathcal{P}_\beta \text{ei}_\beta](y) &= \frac{1}{\beta} \left[\text{ei}_\beta\left(\frac{y}{\beta}\right) + \text{ei}_\beta\left(\frac{y}{\beta} + \frac{1}{2}\right) \right] \\ &= \frac{\text{ei}_\beta(y)}{\beta} \end{aligned}$$

This is a non-polynomial, fractal eigenfunction of \mathcal{P}_β , and, with a bit of elbow-grease, one can find many more. This includes the Takagi functions, and their higher-order analogs, which are, roughly speaking, Takagi functions constructed from polynomials. These all have interesting self-similarity properties under the dyadic monoid.

Unfortunately, one has that $e_{\beta}(x) \neq 0$ when $\beta < 2x$; it won't do as an eigenfunction of \mathcal{L}_β . There is no obvious, simple modification of $e_{\beta}(x)$ that would cause it to be a valid eigensolution of \mathcal{L}_β . Manually installing a factor of $\Theta\left(\frac{\beta}{2} - y\right)$ and then iterating to find the closure leads to the same splatter of step functions as in the case of the polynomials.

Another interesting case arises if one attempts a Fourier-inspired basis. Define

$$e_{\beta;n;l}(x) = \exp i2\pi(2l+1)\beta^n x$$

for integer l . One then obtains a shift sequence

$$[\mathcal{P}_\beta e_{\beta;n;l}](x) = \frac{1}{\beta} e_{\beta;n-1;l}(x) \left(1 + e_{\beta;n;l}\left(\frac{1}{2}\right)\right)$$

This is not a viable candidate for \mathcal{L}_β , as it is again beset by the step function. As a shift sequence, it can be used to construct coherent states that are eigenfunctions of \mathcal{P}_β , having any eigenvalue within the unit disk. Specifically, observe that $e_{\beta;0;l}(1/2) = \exp i\pi(2l+1) = -1$ so that $[\mathcal{P}_\beta e_{\beta;0;l}](x) = 0$ and so the shift sequence terminates after finite iteration. Given a complex value z , construct the coherent state as

$$\phi_{l;z}(x) = \sum_{n=0}^{\infty} z^n e_{\beta;n;l}(x)$$

The shift is then

$$[\mathcal{P}_\beta \phi_{l;z}](x) = \frac{z}{\beta} \sum_{n=0}^{\infty} z^n \left(1 + e_{\beta;n+1;l}\left(\frac{1}{2}\right)\right) e_{\beta;n;l}(x)$$

This is not particularly useful, until one notices that for certain values of β , this contains nilpotent sub-series.

Specifically, fix a value of $n = N$ and consider those values of β for which $e_{\beta;N;l}(1/2) = -1$. This holds whenever β^N is an odd integer, that is, whenever $\beta = (2m+1)^{1/N}$ (and, as always, $\beta \leq 2$). For these special values of β , one has that $[\mathcal{P}_\beta e_{\beta;N;l}](x) = 0$ and so the functions

$$\phi_{l;z;N}(x) = \sum_{n=0}^N z^n e_{\beta;n;l}(x)$$

vanish after N iterations of \mathcal{P}_β . That is, these can be used to form a basis in which \mathcal{P}_β is nilpotent. Conversely, letting m and N be free, the values for which $\beta = (2m+1)^{1/N}$ are dense in the interval $[1, 2)$ and so any β is arbitrarily close to one with a nilpotent function space. These values of β are exactly the same values for which the bit sequences given by eqn 5 eventually terminate in all zeros; i.e. become periodic fixed points with period 1.

The existence of a dense set of fixed points is dual to the the existence of nilpotent densities. That is, one “causes” or “forces” the other to happen. This idea should be further elaborated, as it establishes a duality between countable and uncountable sets, which has an element of curiosity to it.

Presumably, there are special values of β which allow a periodic orbits to originate from a dense set. Such values of β , and such periodic orbits, should then correspond to specific self-similarities of the $\phi_{l;z}(x)$ function, specifically manifesting as cyclic behavior in $(1 + e_{\beta;n+1;l}(\frac{1}{2}))^p$ for some period p . Whether there is some similar manifestation for \mathcal{L}_β is wholly unclear; however, the examination of the periodic orbits of the beta shift, undertaken in a later chapter, will provide a strong clue.

3.4 Complex eigenvalues

Since the operator \mathcal{L}_β is purely real, then if it has a complex spectrum, the eigenvalues and eigenfunctions must come in complex-conjugate pairs. This can make numerical searches and numerical convergence behave in unexpected ways, so some brief commentary is in order.

Assume that there exists some complex-valued eigenfunction $\rho_\lambda(w)$ for fixed, complex eigenvalue λ . Write it's real and complex components as

$$\rho_\lambda(w) = \sigma(w) + i\tau(w)$$

while also writing $\lambda = a + ib$. Then

$$\begin{aligned} [\mathcal{L}_\beta \sigma](w) &= \frac{1}{2} [\mathcal{L}_\beta (\rho_\lambda + \bar{\rho}_\lambda)](w) \\ &= \frac{1}{2} (\lambda \rho_\lambda(w) + \bar{\lambda} \bar{\rho}_\lambda(w)) \\ &= a\sigma(w) - b\tau(w) \end{aligned}$$

Both left and right sides of the above are real. If one had somehow stumbled upon $\sigma(w)$ numerically, as an eigenvector-candidate, then the above admixing of the imaginary component would quickly throw one off the hunt. Thus, a numeric search for complex-valued eigenfunctions must necessarily take into account eigenfunction pairs, with real and imaginary components that mix together as above.

Consistency requires that

$$\begin{aligned} [\mathcal{L}_\beta \tau](w) &= \frac{1}{2i} [\mathcal{L}_\beta (\rho_\lambda - \bar{\rho}_\lambda)](w) \\ &= \frac{1}{2i} (\lambda \rho_\lambda(w) - \bar{\lambda} \bar{\rho}_\lambda(w)) \\ &= a\tau(w) + b\sigma(w) \end{aligned}$$

3.5 The Gelfond-Parry measure

This measure is given by eqn 10 and is given by Gelfond[4] and by Parry[2]. Unfortunately, I find the Russian original of Gelfond's article unreadable, and Parry's work,

stemming from his PhD thesis, is not available online. Therefore, it is of some interest to provide a proof suitable for the current text. A generalization of this proof is used to construct general eigenfunctions.

The easiest route seems to be direct verification that eqn 10 is correct, as opposed to a derivation of eqn 10 from first principles. This is done below, explicitly showing all steps in laborious detail. It's not at all difficult; just a bit hard on the eyes. As before, let $t(x) \equiv t_\beta(x) = \beta x \bmod 1$ be the β -transformation of eqn 8, and $t^n(x)$ the iterated transformation. Let $\Theta(x)$ be the Heaviside step function as always, and to keep notation brief, let $t_n \equiv t^n(1)$. The Gelfond-Parry measure is then

$$v(y) = \sum_{n=0}^{\infty} \frac{\Theta(t_n - y)}{\beta^n}$$

where it is more convenient to write $\varepsilon_n(y) = \Theta(t_n - y)$. The transfer operator \mathcal{M} for the beta-transformation is slightly more convenient to work with than \mathcal{L} for this particular case. It is given by

$$[\mathcal{M}f](y) = \frac{1}{\beta} \left[f\left(\frac{y}{\beta}\right) + f\left(\frac{y+1}{\beta}\right) \Theta(\beta - 1 - y) \right]$$

and we wish to verify that $\mathcal{M}v = v$. Plugging in directly,

$$\begin{aligned} P &= v\left(\frac{y}{\beta}\right) + v\left(\frac{y+1}{\beta}\right) \Theta(\beta - 1 - y) = \sum_{n=0}^{\infty} \frac{1}{\beta^n} \left(\Theta\left(t_n - \frac{y}{\beta}\right) + \Theta\left(t_n - \frac{y+1}{\beta}\right) \Theta(\beta - 1 - y) \right) \\ &= \sum_{n=0}^{\infty} \frac{1}{\beta^n} (\Theta(\beta t_n - y) + \Theta(\beta t_n - 1 - y)) \end{aligned}$$

since $\Theta(ax) = \Theta(x)$ for all constants a , and since $t_n \leq 1$ for all n . These terms simplify, depending on whether t_n is small or large. Explicitly, one has

$$\begin{aligned} \Theta(\beta t_n - 1 - y) &= 0 \text{ if } \beta t_n - 1 < 0 \\ \Theta(\beta t_n - y) &= 1 \text{ if } \beta t_n - 1 > 0 \end{aligned}$$

and so

$$P = \sum_{n=0}^{\infty} \frac{1}{\beta^n} (\Theta(1 - \beta t_n) \Theta(\beta t_n - y) + \Theta(\beta t_n - 1) (1 + \Theta(\beta t_n - 1 - y)))$$

These can be collapsed by noting that

$$\begin{aligned} \beta t_n &= t_{n+1} \text{ if } \beta t_n - 1 < 0 \\ \beta t_n - 1 &= t_{n+1} \text{ if } \beta t_n - 1 > 0 \end{aligned}$$

and so

$$\begin{aligned}
P &= \sum_{n=0}^{\infty} \frac{1}{\beta^n} (\Theta(1 - \beta t_n) \Theta(t_{n+1} - y) + \Theta(\beta t_n - 1) (1 + \Theta(t_{n+1} - y))) \\
&= \sum_{n=0}^{\infty} \frac{1}{\beta^n} (\Theta(t_{n+1} - y) [\Theta(1 - \beta t_n) + \Theta(\beta t_n - 1)] + \Theta(\beta t_n - 1)) \\
&= \sum_{n=0}^{\infty} \frac{1}{\beta^n} (\Theta(t_{n+1} - y) + \Theta(\beta t_n - 1)) \\
&= \beta v(y) - \beta + \sum_{n=0}^{\infty} \frac{\Theta(\beta t_n - 1)}{\beta^n} \\
&= \beta v(y)
\end{aligned}$$

The last sum on the right is just the β -expansion for 1. That is, the β -expansion of x is

$$x = \sum_{n=0}^{\infty} \frac{\Theta(\beta t^n(x) - 1)}{\beta^{n+1}}$$

This is just eqn 6 written in a different way (making use of the equivalence 9). Thus $P = \beta v(y)$ and so $\mathcal{M}v = v$ as claimed.

3.6 Analytic Gelfond-Parry function

The steps performed above can be repeated verbatim for the “rotated” or “coherent” function

$$v_{\beta;z}(y) = \sum_{n=0}^{\infty} z^n \frac{\Theta(t_n - y)}{\beta^n} \quad (20)$$

for some complex-valued z . No changes are required, and the result can be read off directly:

$$\begin{aligned}
[\mathcal{M}v_{\beta;z}](y) &= \frac{v_{\beta;z}(y)}{z} - \frac{1}{z} + \sum_{n=0}^{\infty} z^n \frac{\Theta(\beta t_n - 1)}{\beta^{n+1}} \\
&= \frac{v_{\beta;z}(y)}{z} + C(\beta; z)
\end{aligned}$$

with $C(\beta; z)$ being a constant independent of y . If there are values of β and/or z at which $C(\beta; z) = 0$, then this becomes the eigenequation for \mathcal{M} .

The eigenfunction for \mathcal{L} is the same, up to rescaling of $y \mapsto \beta x/2$. Recycling notation slightly, write

$$v_{\beta;z}(x) = \sum_{n=0}^{\infty} \frac{d_n(x)}{\beta^n} z^n \quad (21)$$

where the $d_n(x)$ are exactly the same digits as defined by Parry, just rescaled for the beta-shift. That is,

$$d_n(x) = \epsilon_n\left(\frac{2x}{\beta}\right) = \Theta\left(\frac{\beta}{2}t_n - x\right) = \Theta\left(T^n\left(\frac{\beta}{2}\right) - x\right) = \begin{cases} 1 & \text{if } x < T^n\left(\frac{\beta}{2}\right) \\ 0 & \text{otherwise} \end{cases}$$

where T the beta-shift map of eqn 4 and eqn 9 is used. The iterated end-point becomes the iterated midpoint:

$$t^n(1) = \frac{2}{\beta} T^n\left(\frac{\beta}{2}\right)$$

Holding both β and x fixed, the summation is clearly convergent (and holomorphic in z) for complex numbers z within the disk $|z| < \beta$. The eigenequation has the same form:

$$[\mathcal{L}_\beta v_{\beta;z}] (x) = \frac{1}{z} v_{\beta;z}(x) + C(\beta; z)$$

where $C(\beta; z)$ is a constant independent of x . Numeric verification reveals we were a bit glib: $C(\beta; z)$ is a constant for $x < \beta/2$ and is zero otherwise!

The interesting limit is where $|z| \rightarrow \beta$ and so its convenient to re-express C in terms of $\zeta = z/\beta$. With some rearrangements, one obtains

$$E(\beta; \zeta) \equiv \zeta \beta C(\beta; \zeta \beta) = -1 + \zeta \sum_{n=0}^{\infty} \zeta^n d_n\left(\frac{1}{2}\right) \quad (22)$$

The primary task is to characterize the zeros of $E(\beta; \zeta)$. This is a straight-forward sum to examine numerically; results will be presented in the section after the next.

3.7 Analytic ergodics

The constant term can be independently derived through a different set of manipulations. Explicitly plugging in eqn 21 into the transfer operator yeilds

$$\begin{aligned} C(\beta; z) &= [\mathcal{L}_\beta v_{\beta;z}] (y) - \frac{v_{\beta;z}(y)}{z} \\ &= \sum_{n=0}^{\infty} \frac{z^n}{\beta^n} \left[\frac{1}{\beta} \left[d_n\left(\frac{y}{\beta}\right) + d_n\left(\frac{y}{\beta} + \frac{1}{2}\right) \right] \Theta\left(\frac{\beta}{2} - y\right) - \frac{1}{z} d_n(y) \right] \end{aligned}$$

Replacing z by $\zeta = z/\beta$ gives

$$\begin{aligned} E(\beta; \zeta) &= \zeta \beta C(\beta; \zeta \beta) \\ &= \sum_{n=0}^{\infty} \zeta^n \left[\zeta \left[d_n\left(\frac{y}{\beta}\right) + d_n\left(\frac{y}{\beta} + \frac{1}{2}\right) \right] \Theta\left(\frac{\beta}{2} - y\right) - d_n(y) \right] \end{aligned}$$

This is holomorphic on the unit disk $|\zeta| < 1$, as each individual d_n is either zero or one; there won't be any poles inside the unit disk. Note that $d_n(y) = 0$ for all $y > \beta/2$, and so one may pull out the step function to write

$$E(\beta; \zeta) = \sum_{n=0}^{\infty} \zeta^n \left[\zeta d_n\left(\frac{y}{\beta}\right) + \zeta d_n\left(\frac{y}{\beta} + \frac{1}{2}\right) - d_n(y) \right] \Theta\left(\frac{\beta}{2} - y\right)$$

confirming the earlier numerical observation that $E(\beta; \zeta)$ vanishes for all $y > \beta/2$.

The bottom equation holds without assuming that $E(\beta; \zeta)$ is independent of y . However, we've already proven that it is; and so a simplified expression can be given simply by picking a specific y . Setting $y = 0$, noting that $d_n(0) = 1$ and cancelling terms, one obtains eqn. 22 again.

Staring at the right-hand side of the sum above, it is hardly obvious that it should be independent of y . In a certain sense, this is not “one equation”, this holds for a continuum of y , for all $0 \leq y \leq 1$. It is an analytic equation tying together the entire subshift. For each distinct y , it singles out three completely different bit-sequences out of the subshift, and ties them together. It is a form of mixing. Alternately, a form of interaction: the bit-sequences are not independent of one-another; they interact. This section attempts to make these notions more precise.

The tying-together of seemingly unrelated sequences seems somehow terribly important. It is tempting to give this some silly name, such as the “fundamental theorem of analytic ergodics”.

Let's be exceptionally clear about the meaning: equation 4 defined a map, the β -shift. Equation 5 defined a bit-sequence, the β -expansion of a real number $0 \leq x \leq 1$, where equation 6 is the defintion of the β -expansion. The set of all such bit-sequences defines the shift. To emphasize the point, its best to compare side-by-side. Copying equation 5, we had

$$k_n(x) = \begin{cases} 0 & \text{if } 0 \leq T_\beta^n(x) < \frac{1}{2} \\ 1 & \text{if } \frac{1}{2} \leq T_\beta^n(x) \leq 1 \end{cases}$$

while

$$d_n(x) = \begin{cases} 1 & \text{if } x < T^n\left(\frac{\beta}{2}\right) = T^{n+1}\left(\frac{1}{2}\right) \\ 0 & \text{otherwise} \end{cases}$$

The iterations are running in opposite directions; this is as appropriate, since the the transfer operator was a push-forward.

It is useful here to return to the language of cylinder sets, as opposed to point dynamics. Recall that the Borel algebra \mathcal{B} was defined as the sigma algebra, the collection of all cylinder sets in the product topology of $\{0, 1\}^\omega$. A subshift is a subset $\mathcal{S} \subset \mathcal{B}$ together with a map $T : \mathcal{S} \rightarrow \mathcal{S}$ that lops off the leading symbol of a given cylinder set but otherwise preserves the subshift: $T\mathcal{S} = \mathcal{S}$. The inverted map T^{-1} is a pushforward, in that it defines the transfer operator, a linear operator $\mathcal{L}_T : \mathcal{F} \rightarrow \mathcal{F}$ on the space \mathcal{F} of all functions $f : \mathcal{S} \rightarrow \mathbb{R}$; explicitly, it is given by $\mathcal{L}_T : f \mapsto f \circ T^{-1}$. Insofar as the d_n arose in the exploration of the transfer operator, it is not surprising that the shift is acting “backwards”.

The problem with point dynamics is that one cannot meaningfully write $T^{-n}(x)$ for a real number, a point x , at least, not without sever contortions that lead back to the Borel algebra. Not for lack of trying; the $T^{-n}(x)$ is called the “Julia set” (to order n) of x : it is the preimage, the set of all points that, when iterated, converge onto x .

Can the analytic relation be restated in terms of cylinder sets? Yes, and it follows in a fairly natural way. The first step is to extend d_n to a map $d_n : \mathcal{S} \rightarrow [0, 1]$. Let $\mu : \mathcal{B} \rightarrow [0, 1]$ be the Bernoulli meaure. Using the Bernoulli mapping 3, the interval $[0, T^n(\beta/2)]$ maps to some cylinder; call it Δ_n . Then, given some cylinder $A \in \mathcal{S}$, define

$$d_n(A) = \mu(A \cap \Delta_n)$$

The rotated (pre-)measure is extended likewise:

$$v(A) = \sum_{n=0}^{\infty} \zeta^n d_n(A)$$

with $\zeta = z/\beta$ as before, recovering the Parry measure by setting $z = 1$. The Parry measure should be invariant under the action of $T^{-1} : \mathcal{S} \rightarrow \mathcal{S}$, and otherwise yeild eqn 22.

Let's check. The proof will mirror the one of the previous section. Here, it is convenient to use the β -transform t instead of the β -shift T . This is primarily a conceptual convenience; the subshift is more easily visualized in terms of the mod 1 map. Otherwise, the same notation is used, but rescaled, so that Δ_n is the cylinder corresponding to the interval $[0, t^n(1)]$.

Recall that for every $A \in \mathcal{B}$ and every $y \in A$, one will find that $y/\beta \in t^{-1}(A)$ and, whenever $y \leq \beta - 1$ that also $(y+1)/\beta \in t^{-1}(A)$. Thus, $t^{-1}(A)$ naturally splits into two parts: the cylinder that maps to $[0, 1/\beta]$, call it D and the complement \bar{D} .

The pushfoward action is then

$$\begin{aligned} v(t^{-1}(A)) &= \sum_{n=0}^{\infty} \zeta^n \mu(\Delta_n \cap t^{-1}(A)) \\ &= \sum_{n=0}^{\infty} \zeta^n [\mu(\Delta_n \cap D \cap t^{-1}(A)) + \mu(\Delta_n \cap \bar{D} \cap t^{-1}(A))] \end{aligned}$$

Two distinct cases emerge. When $t^n(1) < 1/\beta$ then one has that $\Delta_n \cap \bar{D} = \emptyset$. Thus, the second term can be written as

$$\begin{aligned} \mu(\Delta_n \cap \bar{D} \cap t^{-1}(A)) &= \Theta\left(t_n - \frac{1}{\beta}\right) \mu(\Delta_n \cap \bar{D} \cap t^{-1}(A)) \\ &= \Theta\left(t_n - \frac{1}{\beta}\right) \frac{1}{\beta} \mu(\Delta_{n+1} \cap A) \end{aligned}$$

where the second line follows from the first by linearity, and that \bar{D} selected out one of the two branches of $t^{-1}(A)$. Meanwhile, when $t^n(1) > 1/\beta$, then $D \subset \Delta_n$ so that $D \cap \Delta_n = D$. Thus, the first term splits into two:

$$\begin{aligned} \Theta\left(t_n - \frac{1}{\beta}\right) \mu(\Delta_n \cap D \cap t^{-1}(A)) &= \Theta\left(t_n - \frac{1}{\beta}\right) \mu(D \cap t^{-1}(A)) \\ &= \Theta\left(t_n - \frac{1}{\beta}\right) \frac{1}{\beta} \mu(A) \end{aligned}$$

while

$$\Theta\left(\frac{1}{\beta} - t_n\right) \mu(\Delta_n \cap D \cap t^{-1}(A)) = \Theta\left(\frac{1}{\beta} - t_n\right) \frac{1}{\beta} \mu(\Delta_{n+1} \cap A)$$

Reassembling these pieces and making use of $\Delta_0 \cap A = A$ one gets

$$\begin{aligned} v(t^{-1}(A)) &= \sum_{n=0}^{\infty} \frac{\zeta^n}{\beta} \left[\mu(A) \Theta\left(t_n - \frac{1}{\beta}\right) + \mu(\Delta_{n+1} \cap A) \right] \\ &= \frac{1}{z} v(A) - \frac{\mu(A)}{z} + \mu(A) \sum_{n=0}^{\infty} \frac{\zeta^n}{\beta} \Theta\left(t_n - \frac{1}{\beta}\right) \\ &= \frac{1}{z} v(A) + \frac{\mu(A)}{z} E(\beta; z) \end{aligned}$$

with the constant term as before, in eqn 22:

$$\begin{aligned} E(\beta; z) &= -1 + \zeta \sum_{n=0}^{\infty} \zeta^n \Theta\left(t_n - \frac{1}{\beta}\right) \\ &= -1 + \zeta \sum_{n=0}^{\infty} \zeta^n d_n\left(\frac{1}{2}\right) \end{aligned}$$

As before, one has for $z = 1$ that $E(\beta; 1) = 0$ and so $v \circ t^{-1} = v$ is indeed the measure invariant under t^{-1} . Other eigenvalues can be found for those values of z for which $E(\beta; z) = 0$. The task at hand is then to characterize $E(\beta; z)$.

3.8 Exploring $E(\beta; z)$

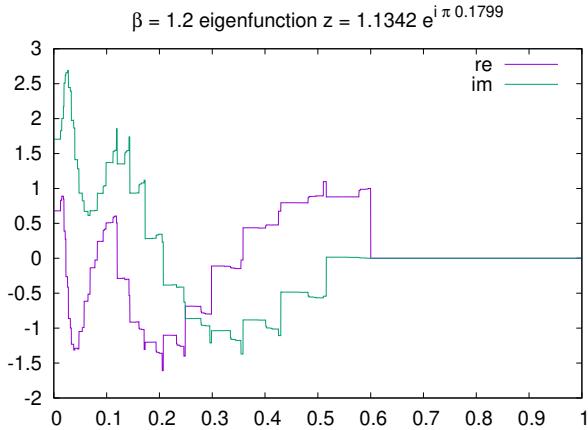

The function is easily explored numerically. It is clearly convergent in the unit disk $|\zeta| < 1$ and has no poles in the disk. For almost all β , there seem to be a countable number of zeros within the disk, accumulating uniformly on the boundary as $|\zeta| \rightarrow 1$. The notion of “uniformly” will be made slightly more precise in the next section, where it is observed that, for certain special values of β , the bit-sequence $d_n\left(\frac{1}{2}\right)$ is periodic, and thus $E(\beta; z)$ is a polynomial. When it is polynomial, there are a finite number of zeros (obviously; the degree of the polynomial), which are distributed approximately uniformly near the circle $|\zeta| = 1$. As the degree of the polynomial increases, so do the number of zeros; but they remain distributed approximately evenly. In this sense, the limit of infinite degree seems to continue to hold.

A handful of selected zeros are listed in the table below. The numbers are accurate to about the last decimal place.

β	z	$ z $	$1/z$
1.8	-1.591567859	1.591567859	-0.6283112558
1.8	-1.1962384 + i 1.216022231	1.705783215	-0.4111213835 - i 0.4179206604
1.8	0.9919147363 + i 1.446092984	1.753590535	0.3225655308 - i 0.4702619429
1.6	-1.063651387 + i 1.008959895	1.466067646	-0.4948701876 - i 0.4694246429
1.4	0.550836432 + i 1.178171082	1.300579822	0.3256481633 - i 0.6965211931
1.2	0.9578845659 + i 0.6073301155	1.134192537	0.7446284155 - i -0.4721187476

These are not particularly meaningful numbers; they just give a flavor for some locations of eigenvalues. Given a zero, the corresponding eigenfunction is also very

Figure 12: Typical Eigenfunction

easily computed. A typical eigenfunction is shown in figure 12; this is for the zero listed in the last row of the table above. Although it is unlike the figure 1, in that it is not strictly decreasing, it does have the same general plateau-like regions. Note that all such eigenfunctions are bounded and generally, differentiable-nowhere.

As the zeros accumulate onto the circle $|\zeta| \rightarrow 1$, there appears to be no way to holomorphically continue the function $E(\beta; z)$ outside of the unit circle. This indicates that there is a lower bound on the possible eigenvalues that can be reached via the eigenfunctions of eqn 21. The lower bound is $\lambda = 1/\beta$; if there are eigenfunctions with smaller eigenvalue, they cannot be written in the form of eqn 21. It is possible that these exist: certainly, that is the suggestion from the special case of $\beta = 2$, where there is a discrete spectrum $\lambda = 2^{-n}$ of real-analytic eigenfunctions, given by the Bernoulli polynomials, and a continuous spectrum filling the unit disk, consisting of square-integrable eigenfunctions. The $\beta \rightarrow 2$ limit of eqn 21 does not approach either of these cases. The description seems incomplete.

3.9 Function field arithmetic

In algebraic number theory, one studies function fields over fields of characteristic p for p a prime number. Multiplication of a field element by an integer n can be taken as the beta transform, with $\beta = n$ integer, acting on the field. Here of course we are working with a field of characteristic zero (the reals), or more properly, the sigma algebra of the Cantor set. None-the-less, what sort of inspiration can be taken?

This is spurred by the observation that the mapping $\mathcal{L}_T : \mathcal{F} \rightarrow \mathcal{F}$ given by $\mathcal{L}_T f = f \circ T^{-1}$ is richer than just just a linear operator. That is, not only does one have the obvious identity $\mathcal{L}_T(af + bg) = a\mathcal{L}_T f + b\mathcal{L}_T g$ for functions f, g and constants a, b , but one also has $\mathcal{L}_T(fg) = \mathcal{L}_T f \cdot \mathcal{L}_T g$ and $\mathcal{L}_T(f/g) = \mathcal{L}_T f / \mathcal{L}_T g$ so that if \mathcal{F} is a function field, then \mathcal{L}_T preserves that structure.

Additional algebraic identities follow from the sigma algebra of the product topol-

ogy. The product topology implies that one can work with function spaces, e.g. measures, for which set intersection and set union behave in a field-like way.

If e belongs to the discrete or continuous spectrum of \mathcal{L}_T , in the sense that $\mathcal{L}_T e = \lambda e$, then it also belongs to the spectrum of any iterate of \mathcal{L}_T , in the sense that $\mathcal{L}_T^n e = \lambda^n e$, and so the \mathcal{L}_T^n form a basis for a vector space. By linearity, one can arrange for operators of arbitrary spectrum, in that one has (at least formally) that

$$\left(\sum_{n=0}^{\infty} a_n \mathcal{L}_T^n \right) e = \sum_{n=0}^{\infty} a_n \lambda^n e$$

for some arbitrary series of numbers a_n (presumably convergent, in order to get reasonable results).

3.10 Iterated transfer operator

To understand the nature of the steady-state solution (the Frobenius-Perron eigenstate), its is worth iterating on the recurrence relation for it, by hand, the first few times. To do this, it is convenient to write it in the form

$$[\mathcal{L}_\beta f](y) = \frac{\Theta(y)}{\beta} [f(\alpha(y)) + f(\omega(y))]$$

where $\Theta(y) = 1$ if $y \leq \beta/2$ else zero; this is a step function to denote the vanishing for the operator for $2y > \beta$. (This differs from the use of Θ as the Heaviside step function in earlier sections; the intent is the same, but the goal is to have a briefer notation here. Which is which should be clear from context.) The functions $\alpha(y) = y/\beta$ and $\omega(y) = \frac{1}{2} + \alpha(y)$ are convenient shorthands for symbolic iteration.

Iterating once gives

$$[\mathcal{L}^2 f](y) = \frac{\Theta(y)}{\beta^2} [\Theta(\alpha(y)) [f(\alpha^2(y)) + f((\omega \circ \alpha)(y))] + \Theta(\omega(y)) [f((\alpha \circ \omega)(y)) + f(\omega^2(y))]]$$

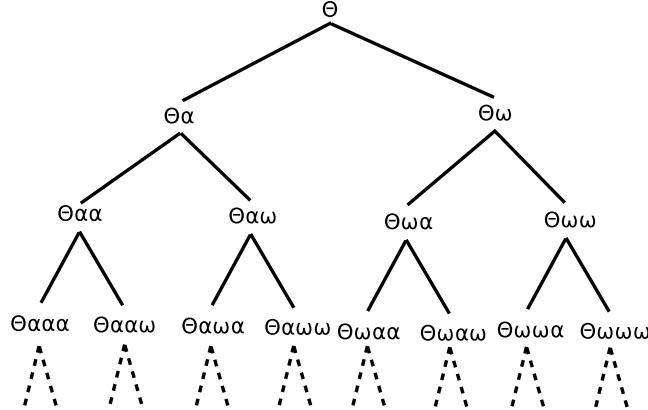

Using a simplified notation $g(y) = f(\alpha(y)) + f(\omega(y))$ allows this to be iterated a third time:

$$[\mathcal{L}^3 f](y) = \frac{\Theta(y)}{\beta^3} [\Theta(\alpha(y)) [\Theta(\alpha^2(y)) g(\alpha^2(y)) + \Theta(\omega \alpha(y)) g(\omega \alpha(y))] + \Theta(\omega(y)) [\Theta(\alpha \omega(y)) g(\alpha \omega(y)) + \Theta(\omega^2(y)) g(\omega^2(y))]]$$

and a fourth time, this time omitting the argument, and the various nesting parenthesis.

$$\begin{aligned} [\mathcal{L}^4 f](y) = & \frac{\Theta(y)}{\beta^4} [\Theta \alpha \Theta \alpha^2 [\Theta \alpha^3 g \alpha^3 + \Theta \omega \alpha^2 g \omega \alpha^2] + \\ & \Theta \alpha \Theta \omega \alpha [\Theta \alpha \omega \alpha g \alpha \omega \alpha + \Theta \omega^2 \alpha g \omega^2 \alpha] \\ & \Theta \omega \Theta \alpha \omega [\Theta \alpha^2 \omega g \alpha^2 \omega + \Theta \omega \alpha \omega g \omega \alpha \omega] \\ & \Theta \omega \Theta \omega^2 [\Theta \alpha \omega^2 g \alpha \omega^2 + \Theta \omega^3 g \omega^3]] \end{aligned}$$

Notice that the primary structure is given by a product of step functions. This is more conveniently visualized as a tree:

For any given iteration, the result is the sum of the vertexes at a given level, while the product of step functions is the product of the step functions in the tree, following the path to each node. Because any particular step function might be zero, it effectively acts to cut off the tree at that location. It is therefore interesting to understand general products of the α and ω functions.

It is convenient to define

$$\gamma_x(y) = \frac{x}{2} + \frac{y}{\beta}$$

so that $\alpha(y) = \gamma_0(y)$ and $\omega(y) = \gamma_1(y)$, so that a general iterated sequence of intermixed α 's and ω 's can be written uniformly in terms of γ . Given a sequence of bits $b_0 b_1 b_2 \dots b_n$ with each b_k being either zero or one, the iterated sequence of functions can be written as

$$(\gamma_{b_0} \gamma_{b_1} \gamma_{b_2} \dots \gamma_{b_n})(y) = \frac{1}{2} \left[b_0 + \frac{b_1}{\beta} + \frac{b_2}{\beta^2} + \dots + \frac{b_n}{\beta^n} \right] + \frac{y}{\beta^{n+1}} \quad (23)$$

So, for example:

$$\alpha^n(y) = \frac{y}{\beta^n}$$

while

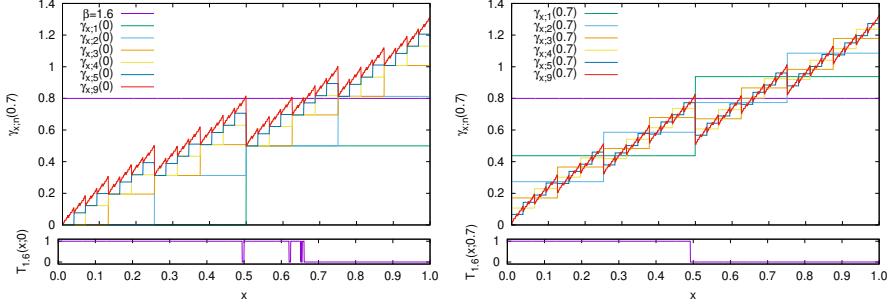

$$\omega^n(y) = \frac{1}{2} + \frac{1}{\beta} \left(\frac{1}{2} + \frac{y}{\beta} \right)$$

and, in general, that

$$\omega^n(y) = \frac{1}{2} \left[1 + \frac{1}{\beta} + \frac{1}{\beta^2} + \dots + \frac{1}{\beta^{n-1}} \right] + \frac{y}{\beta^n}$$

Iterated sequences of pairs of functions, of the form $\gamma_{b_0} \gamma_{b_1} \gamma_{b_2} \dots \gamma_{b_n}$ are reminiscent of de Rham curves, which generalize Cesaro curves and the Koch snowflake. The proper definition of a de Rham curve assumes the sequence is of infinite length, and applies a certain continuity condition, and is generally carried out on the complex plane, so that a continuous, nowhere-differentiable curve results. Here, the curve is distinctly not continuous: eqn 23 is a finite-length form of the shift series 6 which can be visualized as the expander function pdr 12, as shown in figure 8.

Figure 13: Gamma functions

Examples of “typical” gamma functions. Both figures show gamma functions for $\beta = 1.6$; the one on the left shows them for $y = 0$, while the one on the right shows them for $y = 0.7$. Every gamma function is a sequence of plateaus; the zig-zag line is a high-order gamma, essentially showing the limiting case. The tree function is unity whenever all of these curves are below $\beta/2$, and is zero when above. So, for example, for the left figure, the tree function is unity, for all values of x less than about 0.4952; it drops to zero, then returns to unity above $x = 0.5$, until about 0.6221, when it briefly plunges and rises again. Then, another dip, before finally settling to zero near 0.6541. For the right figure, a high-order zig-zag rises above 0.8 somewhere near 0.4914; then $\gamma_{x,1}(0.7)$ rises above 0.8 and stays there, driving the tree function to zero, rendering all other orders irrelevant.

3.11 The Tree Function

Given a bit sequence (b_k) and value for y , define the tree function as

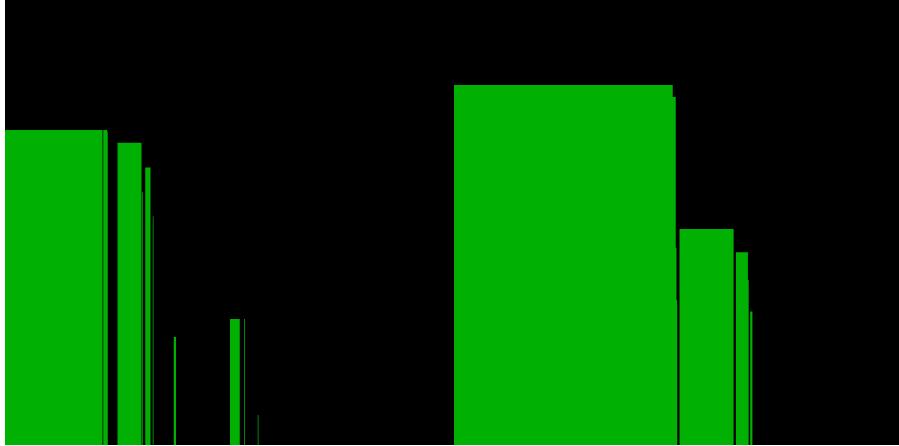

$$T_\beta((b_k); y) = \Theta(y) \prod_{n=0}^{\infty} \Theta(\gamma_{b_0} \gamma_{b_1} \gamma_{b_2} \cdots \gamma_{b_n}(y))$$

For any given fixed sequence of bits and value of y , this function is either zero or one. One way to understand this function is to ask how it varies for fixed β and y , but with the bit sequence coming from the Bernoulli shift of eqn 2, so that $b_n = b_n(x)$. This simplifies notation, so that one can write

$$T_\beta(x; y) = T_\beta((b_k(x)); y) = \Theta(y) \prod_{n=0}^{\infty} \Theta(\gamma_{x,n}(y))$$

with $\gamma_{x,n}(y) = \gamma_{b_0} \gamma_{b_1} \gamma_{b_2} \cdots \gamma_{b_n}(y)$. Its clear that the tree function has maximum support when $y = 0$. Figure 13 shows several gamma functions, and the corresponding tree function that results. Figure 14 shows the x vs. y behavior of the tree functions. Figure 15 shows the β vs. x behavior of the functions. Figure 16 shows a unified visualization of the three preceding charts.

Figure 14: Tree functions

The above illustrate the y vs. x dependence of the tree functions; the left image is for $\beta = 1.4$, the right is for $\beta = 1.6$. Green indicates the regions where the tree function is unity, and black where it is zero. To be clear, this shows $T_\beta(x; y)$ with x and y plotted along the x and y axes. The tree functions shown in figure 13 are just two horizontal slices taken from the right image: a slice along the bottom, and a slice a bit above the middle.

3.12 Haar Basis Matrix Elements

The symmetric Haar wavelets are built from the mother wavelet

$$h(x) = \begin{cases} 1 & \text{for } 0 \leq x < 1/2 \\ -1 & \text{for } 1/2 \leq x < 1 \end{cases}$$

and has individual wavelets given by

$$h_{nj}(x) = 2^{n/2} h(2^n x - j) \quad \text{for } 0 \leq j \leq 2^n - 1$$

The matrix elements of the transfer operator are

$$\langle mi | \mathcal{L}_\beta | nj \rangle = \int_0^1 h_{mi}(x) [\mathcal{L}_\beta h_{nj}](x) dx$$

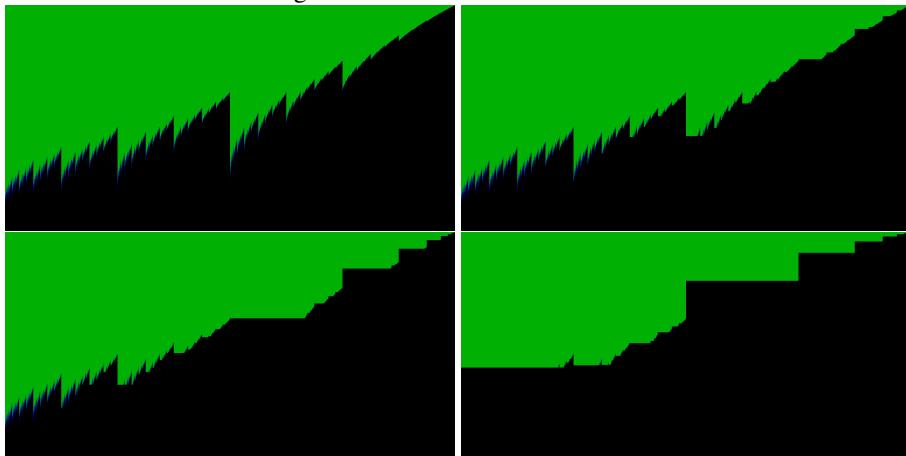

where the operator \mathcal{L}_β is given by eqn 16. Computing these by hand promptly pushes into a big mess. One can obtain explicit expressions, just that they are tedious to obtain. Some preliminary observations include that

$$\langle mi | \mathcal{L}_\beta | nj \rangle = 0 \quad \text{if } \beta \leq i/2^{m-1}$$

because the transfer operator vanishes above $\beta/2$. In the same vein, matrix elements vanish unless

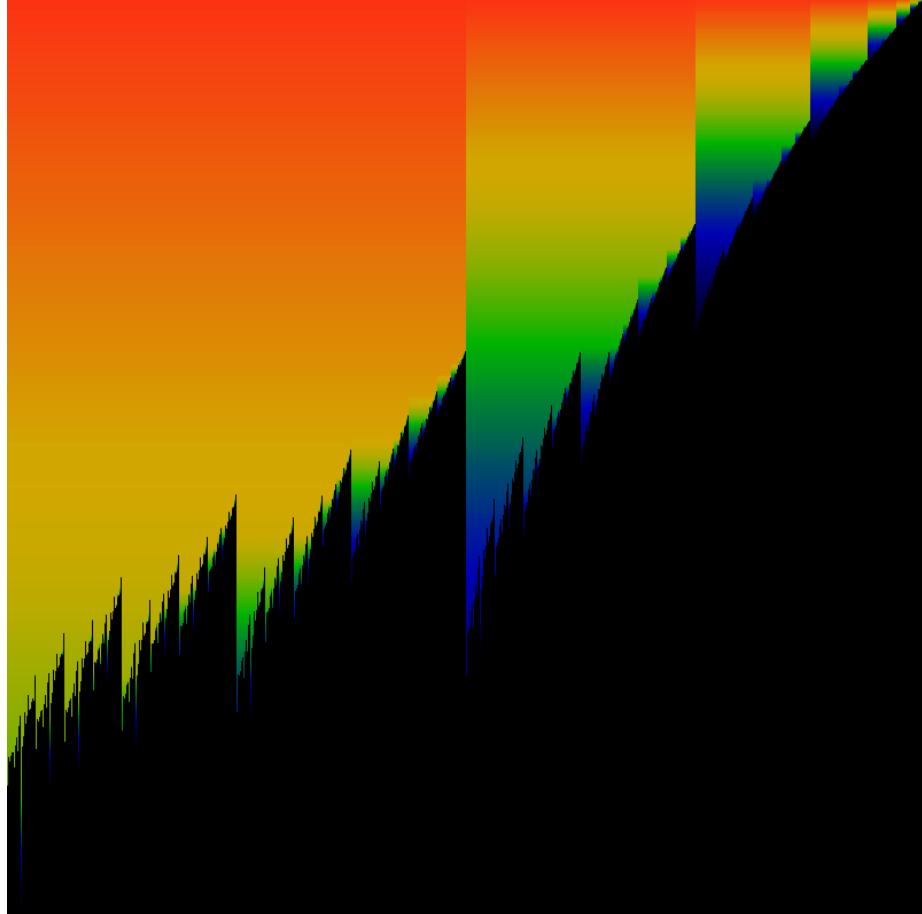

$$\left[\frac{i}{2^m}, \frac{i+1}{2^m} \right] \cap \left[\frac{\beta j}{2^n}, \frac{\beta(j+1)}{2^n} \right] \neq \emptyset$$

Figure 15: Tree function variations

These figures illustrate the β vs. x dependence of the tree function. The upper left shows $T_\beta(x; 0)$, the upper right shows $T_\beta(x; 0.3)$, the lower left shows $T_\beta(x; 0.5)$, the lower right shows $T_\beta(x; 0.7)$. In each case, x runs from 0 to 1 along the x axis, while β runs from 1 to 2 along the vertical axis. As before, green indicates where the tree function is unity, and black where it is zero. The tree functions shown in figure 13 correspond to horizontal slices in the first and last images. Note that many (possibly all???) of the green spikes in the upper-left image reach all the way down to the bottom, although they are mostly much thinner than a pixel and thus not rendered. The vague blue hazing near the spikes is an attempt at anti-aliasing, to highlight the sharpness.

Figure 16: Tree function Unified Visualization

This figure presents a unified visualization of figures 13, 14 and 15. That is, it depicts the $T_\beta(x; y)$ varying all three parameters. The parameter β runs from 1 at the bottom, to 2 at the top. The parameter x runs from 0 to 1, left to right. Because $T_\beta(x; y)$ is either zero or one, the color is used to represent the largest value of y for which $1 = T_\beta(x; y)$. The color coding corresponds to red for $y = 1$, green for $y = 0.5$, blue for $y = 0.25$ and black for $y = 0$. Thus, for example, figure 15 can be obtained directly from this, by setting a given color, “or darker”, to black. The figure 14 represents a single fixed horizontal slice through this figure, with the height of the rectangles in figure 14 corresponding to the color in this figure.

or if

$$\left[\frac{i}{2^m}, \frac{i+1}{2^m} \right] \cap \left[\beta \left(\frac{j}{2^n} - \frac{1}{2} \right), \beta \left(\frac{j+1}{2^n} - \frac{1}{2} \right) \right] \neq \emptyset$$

In all other cases, the Haar wavelets completely fail to overlap, and thus the matrix elements are zero. In addition, only three pairs of wavelets overlap in a non-zero fashion. That is, for a fixed m, n and j , there are at most six different values of i for which the matrix elements are non-vanishing: the first three of these are the values for which

$$\frac{\beta j}{2^n} \in \left[\frac{i}{2^m}, \frac{i+1}{2^m} \right] \text{ or } \frac{\beta(j+\frac{1}{2})}{2^n} \in \left[\frac{i}{2^m}, \frac{i+1}{2^m} \right] \text{ or } \frac{\beta(j+1)}{2^n} \in \left[\frac{i}{2^m}, \frac{i+1}{2^m} \right]$$

and likewise for three more. The observation is that the integral vanishes unless the first wavelet intersects an edge transition of the second wavelet.

The primary failure of this basis is that there is no obvious way to diagonalize the transfer operator in this basis. There is no obvious way of solving it, of finding its eigenfunctions and eigenvalues, other than by brute-force numerical attack.

3.13 Julia Set

Consider the two iterators $a_0(y) = \min\left(\frac{\beta}{2}, \beta y\right)$ and $a_1(y) = \max\left(0, \beta y - \frac{\beta}{2}\right)$. Individually, they are the two arms of the beta shift. Here, they have been separated from each other, so that the full domain $0 \leq y \leq 1$ is allowed. Exploring all possible inter-iterations for these gives the Julia set for the transfer operator: it indicates where a point “came from”, for the iterated transfer operator. There are several related ways to visualize this. One way is to fix y and then, given a bit-sequence (b_n) to compute

$$j((b_n)) = a_{b_0} \circ a_{b_1} \circ a_{b_2} \circ \dots (y)$$

Figure 17 shows a visualization for finite bit-sequences: in essence, the very first few iterations. Although it is similar to figure 9, it is not the same.

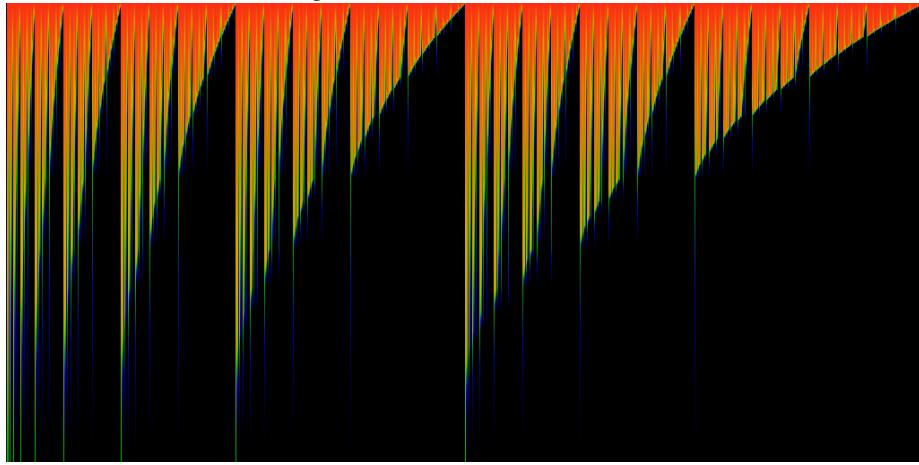

For a related notion, consider the definition of “laps”, from Jeffrey Lagerias *et al.*[24].

4 Hessenberg basis

There is a set of Haar-like wavelets in which the transfer operator is of the form of a Hessenberg operator - that is, the operator becomes almost upper-diagonal, with only one diagonal, just below the main diagonal, that is non-zero. Explicitly, the transfer operator \mathcal{L}_β has matrix entries $[\mathcal{L}_\beta]_{ij}$ such that $[\mathcal{L}_\beta]_{ij} = 0$ whenever $i > j + 1$. A matrix having this form is called a Hessenberg matrix; such matrices have various interesting properties; among others, they generalize the Jacobi matrix. This chapter explicitly constructs an infinite-dimensional Hessenberg matrix, which may now be called a Hessenberg operator.

Hessenberg operators occur naturally in spectral measure theory; some of this will be reviewed in several later chapters. To get a flavor for what is to come: Given a Hessenberg operator, one may construct a system of orthogonal polynomials that

Figure 17: Julia Set visualization

Consider the binary tree of dyadic fractions: that is, the tree whose rows are $1/2$, $(1/4)$, $(1/8 \ 3/8 \ 5/8 \ 7/8)$, ... Consider a function J on this tree. For the head of the tree, set $J(1/2) = \beta$. For the next row, set $J(1/4) = a_0(J(1/2))$ and $J(3/4) = a_1(J(1/2))$. Iterate in this fashion so that $J((2k-1)/2^{n+1}) = a_0(J(k/2^n))$ and $J((2k+1)/2^{n+1}) = a_1(J(k/2^n))$ recursively. This produces a function J taking values on every dyadic fraction $k/2^n$.

In the above figure, β runs from 1 at the bottom to 2 at the top. A single horizontal slice through the image shows a color-coded version of J , with red coding values near 1, green coding values near $1/2$ and blue, fading to black coding values of $1/4$ and less. Note that there are many faint blue lines that extend quite far down, but not all the way down: these form a stair-step. The image is 1024 pixels wide: it shows the first ten rows of the binary tree. Although this image is similar to figure 9, it differs in many details.

provide a basis for square-integrable holomorphic functions on some domain of the complex plane. Such a space is called a Bergman space; in this sense it generalizes the Jacobi operator for real Borel measures. This basis of polynomials in turn allows the Hessenberg operator to be explicitly seen as a shift operator on that domain, with $[Hf](z) = zf(z)$ for H the Hessenberg operator and $f(z)$ a holomorphic function (specifically a Bergman function) on the Bergman domain. But all of this is for later chapters; its mentioned here only to whet the appetite.

TODO: More motivation is needed for this line of reasoning. After all, we have an explicit solution for the eigenfunctions, it is given in expression 20. So, why bother writing the transfer operator as a Hessenberg operator? What does this teach us?

4.1 Hessenberg wavelet basis

The transfer operator \mathcal{L}_β can be fairly easily brought into Hessenberg matrix form. A sequence of orthonormal functions is constructed in this section; when used as a basis, the transfer operator becomes almost upper-diagonal.

The trick to the construction is to define wavelets such that the transfer operator applied each wavelet causes the end-points of the wavelet to exactly line up with the end- or mid-points of previous wavelets, thus avoiding the nasty interval-overlap algebra required with the Haar basis. This is accomplished by carefully picking the midpoint of the next wavelet in the sequence to be located exactly at the discontinuity of the transfer operator applied to the previous wavelet.

The construction proceeds as follows. Let

$$\psi_0(x) = \begin{cases} \frac{1}{\sqrt{\beta/2}} & \text{for } 0 \leq x \leq \beta/2 \\ 0 & \text{for } \beta/2 < x \leq 1 \end{cases}$$

Consider $\mathcal{L}_\beta \psi_0$. It is the sum of two parts: two step-functions; one which is constant for $x \leq \beta/2$ and another that is constant for $\frac{x}{\beta} + \frac{1}{2} \leq \frac{\beta}{2}$. Solving explicitly for the location of the step, it is $x = \beta(\beta - 1)/2$. For convenience, define $m_1 = \beta(\beta - 1)/2$ and $m_0 = \beta/2$. These will anchor a series of midpoints, beginning with $m_{-1} = 0$. Using the midpoint m_1 , construct the wavelet

$$\psi_1(x) = \begin{cases} \frac{1}{m_1} \sqrt{\frac{m_1(m_0 - m_1)}{m_0}} & \text{for } 0 \leq x \leq m_1 \\ \frac{-1}{m_0 - m_1} \sqrt{\frac{m_1(m_0 - m_1)}{m_0}} & \text{for } m_1 < x \leq m_0 \\ 0 & \text{for } m_0 < x \leq 1 \end{cases}$$

Note that this is normalized to unit length: $\int_0^1 |\psi_1(x)|^2 dx = 1$ and that it is explicitly orthogonal to the first: $\int_0^1 \psi_1(x) \psi_0(x) dx = 0$.

Consider $\mathcal{L}_\beta \psi_1$. As always, it is the sum of two parts. The midpoint of ψ_1 is at $m_1 = \beta(\beta - 1)/2$ and this mid-point is mapped to one of two different places. If $m_1 < 1/2$ then it is mapped to $m_2 = \beta m_1$ else it maps to $m_2 = \beta(m_1 - 1/2)$. Thus, if

$m_1 < 1/2$, define

$$\psi_2(x) = \begin{cases} 0 & \text{for } 0 \leq x \leq m_1 \\ \frac{1}{(m_2-m_1)} \sqrt{\frac{(m_2-m_1)(m_0-m_2)}{m_0-m_1}} & \text{for } m_1 \leq x \leq m_2 \\ \frac{-1}{(m_0-m_2)} \sqrt{\frac{(m_2-m_1)(m_0-m_2)}{m_0-m_1}} & \text{for } m_2 < x \leq m_0 \\ 0 & \text{for } m_0 < x \leq 1 \end{cases}$$

else define

$$\psi_2(x) = \begin{cases} \frac{1}{m_2} \sqrt{\frac{m_2(m_2-m_1)}{m_1}} & \text{for } 0 \leq x \leq m_2 \\ \frac{-1}{(m_1-m_2)} \sqrt{\frac{m_2(m_2-m_1)}{m_1}} & \text{for } m_2 \leq x \leq m_1 \\ 0 & \text{for } m_1 < x \leq 1 \end{cases}$$

Because each end of the interval on which ψ_2 is non-zero lies entirely within one of the constant arms of ψ_1 , one has, by construction, that $\int_0^1 \psi_2(x) \psi_1(x) dx = 0$ (and, of course, $\int_0^1 \psi_2(x) \psi_0(x) dx = 0$.)

The rest of the basis can be constructed iteratively, based on these examples. The midpoints are given by iterating 4 on $m_0 = \beta/2$, so that $m_p = T_\beta(m_{p-1}) = T_\beta^p(m_0)$ is the p 'th iterate of $\beta/2$. Let m_l be largest midpoint smaller than m_p (and $l < p$); let m_u be the smallest midpoint larger than m_p (and $l < p$). Let $m_{-1} = 0$ initiate the sequence by providing the smallest-possible “midpoint”; $m_0 = \beta/2$ already provides the largest possible.

Then define

$$\psi_p(x) = \begin{cases} 0 & \text{for } 0 \leq x \leq m_l \\ \frac{C_p}{(m_p-m_l)} & \text{for } m_l \leq x \leq m_p \\ \frac{-C_p}{(m_u-m_p)} & \text{for } m_p < x \leq m_u \\ 0 & \text{for } m_u < x \leq 1 \end{cases} \quad (24)$$

By construction, this has the property that $\int_0^1 \psi_{p+1}(x) \psi_n(x) dx = 0$ for any $n < p + 1$. The normalization constant is

$$C_p = \sqrt{\frac{(m_p - m_l)(m_u - m_p)}{m_u - m_l}}$$

which is determined by requiring that $\int_0^1 |\psi_p(x)|^2 dx = 1$.

4.2 Matrix Elements

The above-defined basis provides the Hessenberg representation for the transfer operator. Defining

$$\langle n | \mathcal{L}_\beta | m \rangle = \int_0^1 \psi_n(x) [\mathcal{L}_\beta \psi_m](x) dx \quad (25)$$

this has the expected Hessenberg form, in that

$$\langle n | \mathcal{L}_\beta | m \rangle = 0 \quad \text{for } n > m + 1$$

This is just one diagonal short of being actually solvable. A visualization of the matrix elements is shown in figure 18.

4.3 Completeness

The Hessenberg basis construction gives a countable set of ψ_n that is an orthonormal basis on the unit interval: $\int_0^1 \psi_m(x) \psi_n(x) dx = \delta_{mn}$. Are they complete? Obviously the $\{\psi_n\}$ cannot be complete on the unit interval, as they all vanish for $\beta/2 < x$. Perhaps they are complete on the interval $[0, \beta/2]$, where they are already orthonormal: $\int_0^{\beta/2} \psi_m(x) \psi_n(x) dx = \delta_{mn}$.

A numerical exploration shows that the midpoints m_p are dense in the interval $(0, \beta/2)$, and so this suggests that the basis should be considered to be “sufficiently complete” on the interval $[0, \beta/2]$. The distribution of the m_p follow exactly the distribution of the invariant measure. Convergence is uniform to the same degree that the midpoints “eventually” fill in and become dense in some interval. Renyi[1] and Parry[2] do more: they show that the midpoint process is ergodic (Parry points out that it’s weakly mixing), and provide a formal proof that the distribution is one and the same as the invariant measure.

The above has some exceptions: there are some values of β for which the midpoint m_0 iterates $x = 1/2$, wherupon iteration stops (i.e. iterates to zero), or becomes cyclic (forming a periodic orbit). Which is which depends on how the point $1/2$ is treated by the map. These values of β are potential “trouble spots”, and are explored in greater detail in the next chapter. They are dense in the interval $1 < \beta < 2$, but they form a countable set that can be taken to be of measure zero. Thus, most “most” values of β are not problematic. Excluding the trouble spots, the Hessenberg basis can be taken to be complete.

Clearly, the ψ_n span some subspace; do they span the Hilbert space $L_2[0, \beta/2]$ of square-integrable functions on the interval $[0, \beta/2]$? To what degree can one legitimately write

$$\delta(y - x) = \sum_{n=0}^{\infty} \psi_n(y) \psi_n(x)$$

as a resolution of the identity?

The question of completeness dogs some “obvious” assumptions one wants to make. For example, if the set of states is complete, and the resolution of the identity holds, then one expects that the transfer operator resolves to the iterated function:

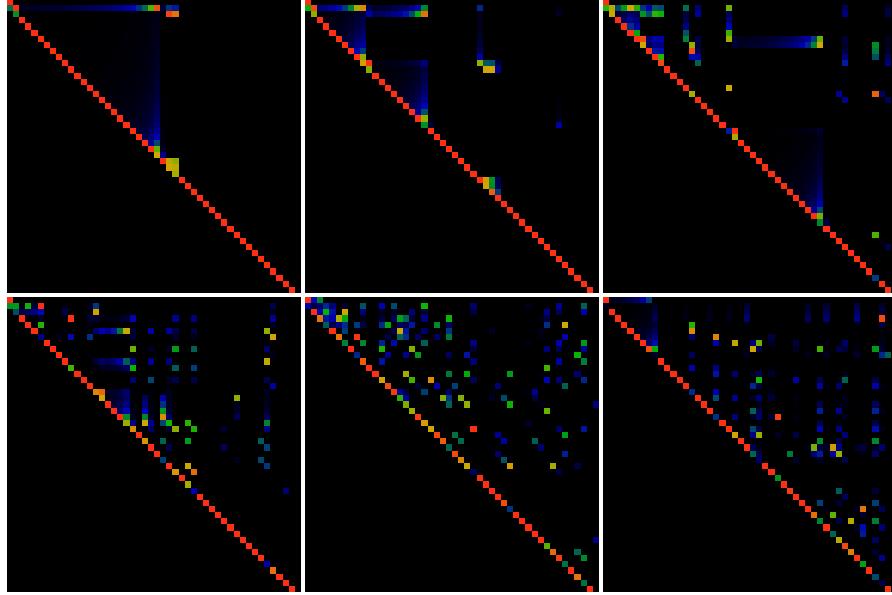

$$\delta(y - (\beta x \bmod 1)) = \sum_{n=0}^{\infty} \sum_{m=0}^{\infty} \psi_n(y) \langle n | \mathcal{L}_{\beta} | m \rangle \psi_m(x)$$

It is fun to verify that the world works as one expects it to work: the above can be verified to hold numerically, for sums limited to a finite cutoff.

4.4 Numerical Eigenvalues

Given the apparent sparsity visible in figure 18, one might think that the eigenvalue problem is fairly stable, numerically. It is not all that much. Numerical exploration

Figure 18: Hessenberg Operator Matrix Elements

Six illustrations of the absolute value of the matrix elements $\langle n | \mathcal{L}_\beta | m \rangle$ for the transfer operator \mathcal{L}_β for (left to right, top to bottom) $\beta = 1.1, 1.2, 1.3, 1.6, 1.90, 1.998$ and $0 \leq n, m < 48$ in the Hessenberg basis. The red color represents values of 0.66 or larger, green represents values of 0.33 and blue and darker correspond to 0.16 or less. Almost all matrix elements are in fact precisely zero; black pixels in these images correspond to matrix elements that are zero. Note that the almost all of the diagonal matrix elements are exactly zero: that is $\langle n | \mathcal{L}_\beta | n \rangle = 0$ for most n . The bright-red pixels are just below the diagonal: for most n , one has that $\langle n+1 | \mathcal{L}_\beta | n \rangle \gtrsim 0.5$ with the occasional blueish pixel suggesting a smaller value. These two, taken together, suggests that the eigenvalue spectrum is rapidly decreasing. The first few images suggests a regular pattern that gets increasingly compressed and chaotic as β increases. More-or-less the same structure prevails if one instead zooms out to look at the 600x600 submatrix; animating with fine-grained steps in β does not result in an interesting animated movie.

suggests that the spectrum is on or near a circle lying in the complex plane², of radius $|\lambda| = 1/\beta$ (ignoring, that is, the leading eigenvalue of 1, which is easily found).

To be clear, this is a numerical exploration of the $N \times N$ principle submatrix of $\langle n | \mathcal{L}_\beta | m \rangle$. The eigenvalue problem being posed is to find a vector $\vec{v} = (v_k)_{k=0}^N$ that solves

$$\sum_{m=0}^N \langle n | \mathcal{L}_\beta | m \rangle v_m = \lambda v_n$$

for some constant λ (with the set of possible λ depending on N , of course).

There are various pitfalls in extrapolating from this to the $N \rightarrow \infty$ limit. For the next few paragraphs, consider only some notion of a “minimal” extension from finite N to the limit. That is, for each finite N , one has a finite set of eigenvalues and eigenvectors. In the limit, there may be accumulation points: points where the eigenvalues accumulate to a limit point, in a standard topological sense. What should that topological space be? For finite N , all eigenvectors are explicitly summable, and thus can be taken to belong to any Banach space ℓ_p . One may as well take $p = 2$ the Hilbert space, and normalize the eigenvectors \vec{v} so that $1 = \sum_{m=0}^N v_m^2$.

For finite N , it appears that “most” eigenvalues λ are “near” the circle $|\lambda| = 1/\beta$, and that they seem to be very uniformly distributed around this circle. The numerical results indicate that in the limit $N \rightarrow \infty$, that the scare-quotes “most” becomes “almost all” in the usual sense. Similarly, “near” appears to mean that for any given λ at finite N , one has that $|\lambda| - 1/\beta \sim \mathcal{O}(1/N)$. As to uniformity, it seems that the spacing between nearest neighbors is also $\mathcal{O}(1/N)$, and that there are no “premature” accumulation points: eigenvalues never get any closer than $\mathcal{O}(1/N)$, either.

Thus, the minimal closure, the minimal extrapolation to limit points strongly suggests that the limit points really do lie, uniformly distributed, on the circle $|\lambda| = 1/\beta$. Then, writing a given accumulation point as $\lambda = \beta^{-1} \exp 2\pi i \phi$, what the numerics do not reveal, or, at least, do not easily reveal, is whether the allowed values of ϕ are always rational, irrational or might have some other regular structure. The numerical exploration does suggest that the eigenvalues are dense on the circle. Certainly it is the case Hessenberg basis is countable, an so one would expect the eigenvalue spectrum obtained in this way to be at least countable, as well. Whether it is also uncountable seems unknowable in this naive sense.

This question is interesting because if only rational ϕ are allowed, then the decaying eigenfunctions belong to a cyclic group, and exhibit an exact form of Poincaré recurrence as they decay. If irrational ϕ are allowed, then the decaying eigenfunctions are at least ergodic.

For $\beta = 2$, the β -transform is the Bernoulli shift, the transfer operator is solvable, and the spectrum is exactly known. This has been explored by various authors[29]. I’ve written extensively about this spectrum and the eigenvalues in other texts[30, 31, 32].

²This was confirmed with both GSL `gsl_eigen_nonsymmv()` and Lapack DHSEQR solvers, exploring the principle submatrix of various sizes, up to about 2000×2000 entries. Both systems agree to at least six decimal places, if not more. Both show sporadic eigenvalues off the circle, but these are not numerically stable; ergo, the only valid eigenvalues are those on the circle. The matrix entries were constructed using the midpoint algorithm, described in the last section. To verify that they are accurate, several techniques were used: numerical integration to confirm orthogonality, and the use of the GnuMP multi-precision library to push up accuracy.

To recap, it takes several forms, depending on the function space that one chooses to work in. If one restricts oneself to polynomial eigenfunctions, then the spectrum is real, non-negative (it has an extensive kernel) and has eigenvalues of 2^{-n} for all n . The eigenfunctions are the Bernoulli polynomials. Restricting to square-integrable eigenfunctions, the spectrum continuous, having eigenvalues on the unit disk in the complex plane. The continuous-spectrum eigenfunctions (for eigenvalues other than 2^{-n}) can be understood in several ways: if forced to be differentiable, then they are not bounded (they diverge) at the endpoints of the interval. If forced to be bounded, then they are fractal (non-smooth) over the entire interval. The unitary spectrum corresponds to differentiable-nowhere eigenfunctions (wait, or continuous-nowhere? I forget.)

A pair of plausible, numerically-extracted eigenfunctions are shown in image 19.

Presumably, the spectrum can be related to the lap-counting function, given by Lagarias[24].

4.5 (Non-)Unitarity

The numerical results suggest a hypothesis that perhaps some fragment of \mathcal{L}_β is unitary, as it is ordinarily the case that when eigenvalues appear on the unit circle, it is because an operator is unitary. That does not seem to be the case here. Specifically, define the Frobenius-Perron eigenvector ρ as the one satisfying $\mathcal{L}_\beta \rho = \rho$ and normalizing it to unit length, so that $\|\rho\| = 1$ in the Hilbert (mean-square) norm. Define the reduced operator \mathcal{R}_β in terms of the matrix elements

$$\frac{1}{\beta} \langle n | \mathcal{R}_\beta | m \rangle = \langle n | \mathcal{L}_\beta | m \rangle - \langle \rho | n \rangle \langle \rho | m \rangle$$

That is, it is just the beta shift operator, with the Frobenius-Perron eigenvector removed, so that $\mathcal{R}_\beta \rho = 0$. Its rescaled, so that the remaining eigenvectors of \mathcal{R}_β lie on the unit circle. Is this operator unitary in any way? That is, might either $\mathcal{R}_\beta \mathcal{R}_\beta^\dagger$ or $\mathcal{R}_\beta^\dagger \mathcal{R}_\beta$ be the identity? Here, the dagger \dagger is just the transpose, as \mathcal{R}_β is purely real. Numerical exploration clearly shows that \mathcal{R}_β is neither unitary on the left nor on the right. Not a surprise, but does leave the understanding of \mathcal{L}_β in a curious situation.

Perhaps it is not enough to subtract the invariant measure: The zeros of the formula 22 lying inside the disk must be subtracted as well. There seems to be a cutable number of these; the subtraction won't be straight-forward.

4.6 Invariant Measure

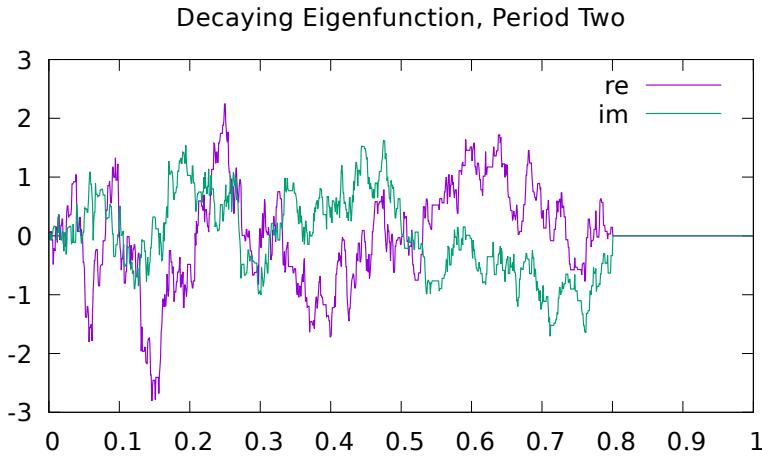

Let v_n be the Ruelle-Frobenius-Perron eigenvector in the Hessenberg basis. That is, let v_n be the vector that solves

$$\sum_{m=0}^{\infty} \langle n | \mathcal{L}_\beta | m \rangle v_m = v_n \quad (26)$$

This is readily computed numerically, and it is straightforward to verify the numerics by confirming that

$$\rho(x) = \sum_{m=0}^{\infty} v_m \psi_m(x)$$

Figure 19: Decaying Eigenfunction, Period Two

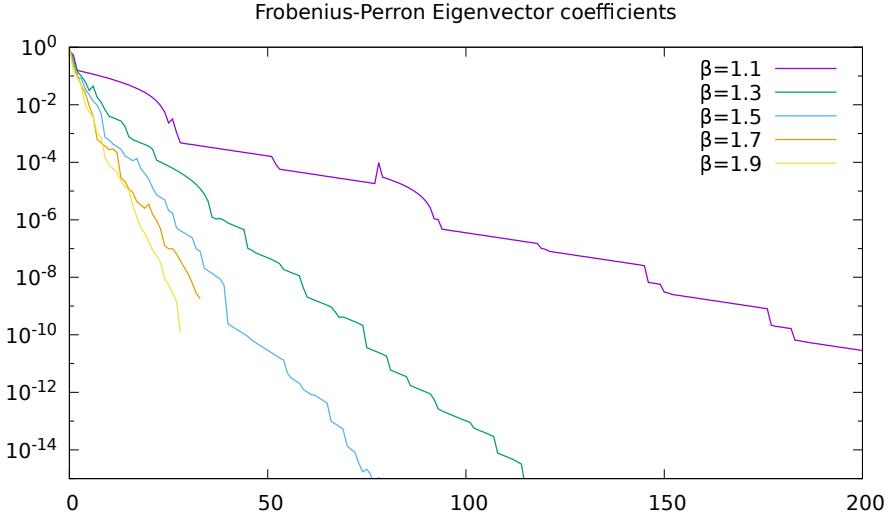

This shows a numerically-computed decaying eigenfunction of period two, for $\beta = 1.6$. It is period two, in that it corresponds to an eigenvalue of $\lambda = -1/\beta = -0.625$, so that after one iteration of \mathcal{L}_β , the sign flips. This can be confirmed, numerically: after one iteration, the sign really does flip, to within numerical errors. This was computed by numerically diagonalizing the 861×861 matrix given by the lowest terms of eqn 25, and then graphing the eigenvector closest to $\lambda = -0.625$ (The GnuMP library was used to provide the required level of precision in the calculations.)

Although this figure is drawn with curves labeled “real” and “imaginary”, this is a bit fantastic, and is a numeric artifact. For any period-two eigenfunction, the real and imaginary parts would have no coupling, and would be independent of each other; either one could be set to zero and one would still have a valid eigenfunction. This differs from the case of period-three and higher, where the real and imaginary parts are expected to mix. (Nor are the two components orthogonal, as one might expect.) The eigenfunction is also fantastic in that only slightly different numerics result in a completely different eigenfunction being computed. Even the functions resulting from diagonalizing the 863×863 matrix differ fair amount from those arising from the 861×861 matrix; there’s only a general resemblance. This is not entirely surprising: the magnitude of the basis coefficients decays very slowly; even at 861, that are still on the order of 10^{-3} , and thus contribute strongly.

Computed eigenfunctions for period-three are not dissimilar, nor are the ones for other values of β . They do seem to start having the general oscillatory character of $\sin(1/x)$ as $\beta \rightarrow 1$, but its not clear if this is a numeric artifact, or something real. The wildness of these functions contrast sharply with the seemingly tame $\lambda = 1$ eigenfunctions shown in figure 1. Compare to figure 12, which paves the way.

Figure 20: Frobenius-Perron Eigenvector Coefficients

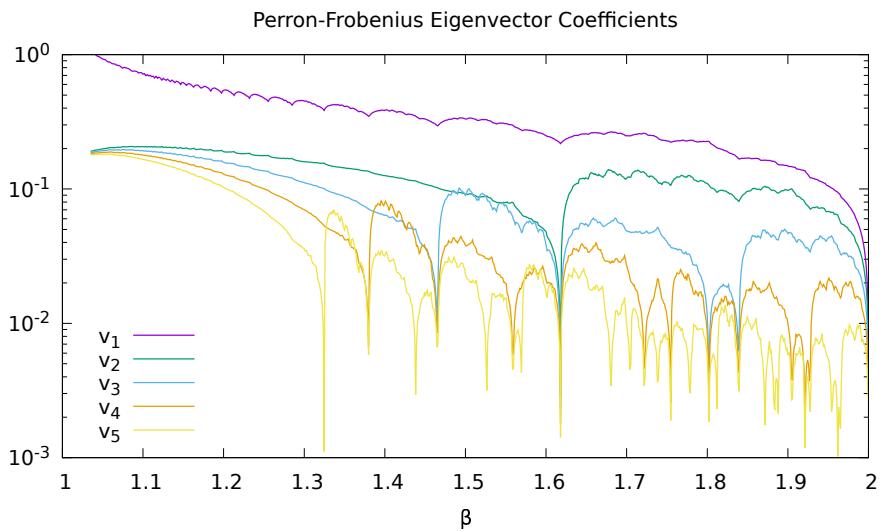

The coefficients v_n solving eqn 26 as a function of n , for various values of β . Note that the coefficients are all real and positive. These can be obtained in two different ways: either by numerically diagonalizing the matrix equation of 26 or by numerically integrating $\int_0^1 \rho(x) \psi_n(x) dx$. Either method gives the same results; diagonalization is far, far quicker. The slope appears to go as approximately $v_m \sim C\beta^{-m}$ with $C = 0.02$ roughly.

is the invariant measure of equations 17,18, with the $\psi_k(x)$ being the wavelets of eqn 24. This expansion seems to ‘make sense’, as the discontinuities seen in the graph of $\rho(x)$ in figure 1 occur at exactly the midpoints m_p and the size of each discontinuity appears to get smaller as p gets larger. Given that the wavelet $\psi_p(x)$ has its central discontinuity at m_p and is bounded on left and right by midpoints of lower order, this expansion seems to be very natural. This is supported by the diagram 20, which depicts the values of v_n as a function of n for selected values of β . These values of v_n are real, positive, and quickly get small; there are no difficulties or issues of convergence.

Is there some simple expression for the values of v_n as a function of β ? If so, it must be formed using some sort of fractal shift. Figure 21 illustrates v_1 through v_5 .

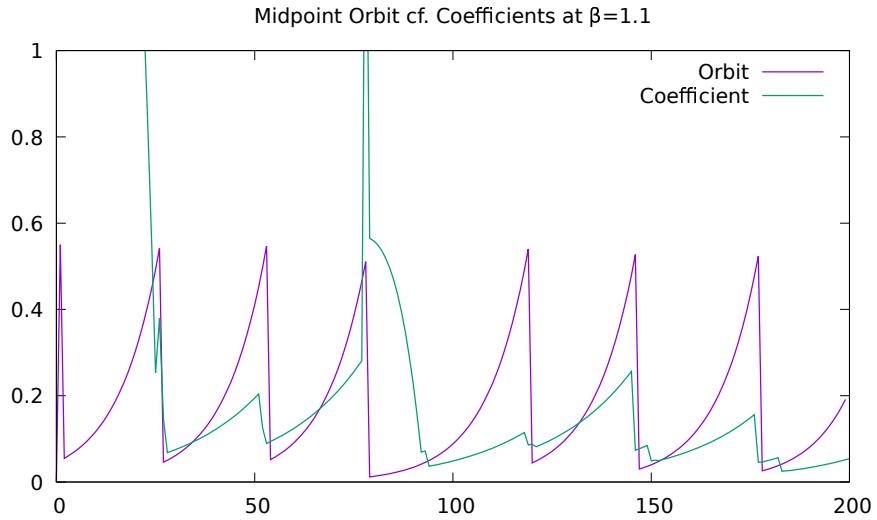

The orbit of the midpoint is correlated with value of the coefficients, illustrated in figure 22. The midpoint polynomial for $m_p = T_\beta^p(\beta/2)$, given in eqn 28, is compared to $v_m \beta^m$. It can be seen to ‘line up’. The two are somehow related; its not clear just how.

Figure 21: Perron-Frobenius Eigenvector Coefficients

This figure shows v_1 through v_5 as β is varied. The most prominent spike is located at $\beta = \varphi = 1.618 \dots$ the Golden Ratio. All spikes correspond to orbits that terminate in a fixed point after a finite number of iterations. The root cause and location of the spikes is shown in figure 23.

Figure 22: Orbits and Coefficients

This figure compares the midpoint orbit to the coefficients, providing evidence for the hypothesis stated in the text. The midpoint orbit is just $m_p = T_\beta^p(\beta/2)$. Because $\beta = 1.1$ in this figure, the discontinuities are infrequent and appear to be quasi-regular (they are ultimately fully chaotic), as the midpoint mostly just walks up to where it is knocked down again. The “coefficient” curve is a graph of $10v_p\beta^p$ for p running along the horizontal axis. This is the same v_p as discussed in the text, and previously shown in figure 20. Here, its rescaled by its asymptotic behavior, and a constant of 10 to place it on the same vertical scale. The discontinuities clearly line up. The relationship is clearly non-trivial.

4.7 Generating Function

The truncated ordinary generating function associated with the eigenvector of eqn 26 is

$$G_N(z) = \sum_{m=0}^N v_m z^m$$

with the ordinary generating function being the limit $N \rightarrow \infty$. A numerical study of this function indicates that most of the N zeros of G_N are arranged approximately on a circle of radius β . The arrangement appear to be quite uniform, with more-or-less equidistant spacing of the zeros. As N increases, it seems that more of the zeros get closer to the circle, although the numerical instabilities associated with double-precision math make this difficult to control; an arbitrary-precision eigenvalue solver would be needed to confirm this behavior.

If this behavior persists, and it seems that it will, then the limit $N \rightarrow \infty$ cannot be taken, and the ordinary generating function, as an analytic function, can't exist, *per se*, as it would be uniformly zero inside the disk. Thus, the zeros already found by means of eqn 22 seem to come to the rescue: these are located inside the disk; perhaps these are masquerading as “numerical instabilities”, and should be taken as actually existing, and not spurious.

In the next chapter, it will be seen that circles of zeros in the complex plane is a recurring theme. This suggests a hypothesis that somehow it might hold that

$$\sum_m v_m (\beta z)^m \sim z^{N+1} - \sum_k b_k z^k$$

as both sides have zeros arranged in circles of unit radius. The right hand side is defined and explored in detail in the next chapter. Superficially, this hypothesis is clearly false: coefficients on the left are all real and positive; coefficients on the right - the b_k , are bits, either zero or one. Yet both exhibit a circle of zeros.

XXX This section is awkward. Revise it or cut it.

4.8 Givens rotations

An open question: A Hessenberg matrix can be brought to solvable form by applying a sequence of Givens rotations. Is the sequence of angles that appear in these rotations meaningful in any way, or are they just some form of uninteresting junk?

5 Periodic Orbits

The iteration of the midpoint $m_0 = \beta/2$, that is, the iterated series $m_n = T_\beta^n(\beta/2)$ is ergodic in the unit interval, for almost all values of β . However, for certain values of β , the midpoint iterates will hit the point $x = 1/2$ where the β -shift map has a discontinuity. Here, iteration stops: at the next step, this point is defined to iterate to zero, in eqn 4. Zero is a fixed point, and so there is nowhere further to go. This section explores these special values of β .

Aside from the definition in eqn 4, one can consider the modified map, where the less-than sign has been altered to a less-than-or-equals:

$$T_{\beta}^{\leq}(x) = \begin{cases} \beta x & \text{for } 0 \leq x \leq \frac{1}{2} \\ \beta(x - \frac{1}{2}) & \text{for } \frac{1}{2} < x \leq 1 \end{cases}$$

In this map, the point $x = 1/2$ iterates to $\beta/2$, which is just the initial midpoint itself. In this case, the halted orbits become periodic orbits. There is a third possibility, to simply remove the points 0, 1 and $1/2$ from the domain:

$$T_{\beta}^{<}(x) = \begin{cases} \beta x & \text{for } 0 < x < \frac{1}{2} \\ \beta(x - \frac{1}{2}) & \text{for } \frac{1}{2} < x < 1 \end{cases}$$

In this case, if the midpoint iterates to $1/2$, it can be taken to simply have wandered out of the domain of validity. The word “wander” is used here in the technical sense: The map $T_{\beta}(x)$ is dissipative in two different senses: first, in the obvious sense, the points $\beta/2 < x$ wander away after exactly one iteration; secondly, the mid-point iterates wander down to zero, never to return, unless they are made explicitly periodic with $T_{\beta}^{\leq}(x)$.

All three variants can be considered together, so that the “true” beta shift is taken as the quotient space or identification space[33] of the three variants, in the strict topological sense of a quotient space. Thus, interestingly, for the beta shift, the periodic orbits and the fixed point both belong to the same equivalence class. This has some interesting implications when one compares the beta shift to other iterated maps, such as the logistic map, which have non-trivial stable regions. Topologically, it would seem that one can perform a kind of surgery, attaching stable regions exactly into those spots where, in the beta shift, one has an equivalence class. This solves (at least for me) the long-standing problem of exactly how to properly describe the topological conjugacy between different kinds of iterated maps.

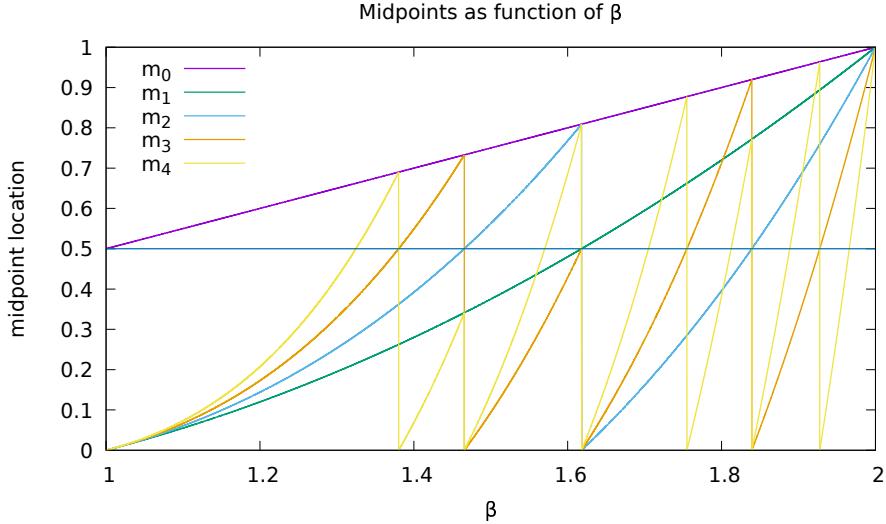

5.1 The β -generalized Golden Ratio

The first periodic orbit can be found when $\beta = \varphi = (1 + \sqrt{5})/2$ the Golden Ratio. In this situation, one has that $m_0 = \varphi/2$ and $m_1 = 1/2$. At this location, further iteration breaks down. That is, $m_2 = T_{\varphi}(m_1)$ can either be taken to be $m_2 = 0$ or $m_2 = m_0$. For lack of a better term, this can be called a “trouble spot”.

Trouble spots occur whenever the p 'th iterate $m_p = T_{\beta}^p(m_0)$ lands at the discontinuity, so that one may take either $m_p = 0$ or $m_p = m_0$. For $p = 3$, there are two such trouble spots, which occur when either $\beta^3 - \beta^2 - 1 = 0$ or when $\beta^3 - \beta^2 - \beta - 1 = 0$. These correspond to the values of $\beta = 1.465571231876768\cdots$ and $\beta = 1.839286755214161\cdots$.

Where else are such spots located? Consider, for example, $m_4 = T_{\beta}^4(m_0)$, and consider the movement of m_4 as β is swept through the range $1 < \beta < 2$. This is shown in figure 23. As made clear in the image, three new degenerate points appear. These are located at $\beta = 1.380327757\cdots$ and $\beta = 1.754877666\cdots$ and $\beta = 1.927561975\cdots$,

Figure 23: Location of Midpoints

This rather busy image illustrates the location of the first five midpoints, m_0, m_1, \dots, m_4 as a function of β . The locations of the discontinuities are termed “trouble spots”; the first trouble spot occurring for m_2 at $\beta = \varphi$. The midpoint m_3 has two new trouble spots at $\beta = 1.465 \dots$ and $\beta = 1.839 \dots$; the trouble spot at $\beta = \varphi$ being disallowed, as it already lead to a termination of midpoint iteration. The midpoint m_4 has three new trouble-spots. That is, trouble spots arise on a pruned binary tree: one generally expects new spots to occur on the left and right of the immediate predecessor, unless they’re already been encountered before.

which are the real roots of $\beta^4 - \beta^3 - 1 = 0$ and $\beta^4 - \beta^3 - \beta^2 - 1 = 0$ and $\beta^4 - \beta^3 - \beta^2 - \beta - 1 = 0$ respectively.

Following a similar suggestion by Dajani[3], numbers of this kind may be called “generalized golden means”. Unfortunately, the term “generalized golden mean” is in common use, and is applied to a variety of different systems. Not all are relevant; one that is, is given by Hare *et al.*[34] who provide series expansions for the real roots of $\beta^p - \sum_{k=0}^{n-1} \beta^k = 0$; these are known as the n-bonacci constants (Fibonacci, tribonacci, tetranacci, etc.). Stakhov[35] considers $\beta^{p+1} - \beta^p - 1 = 0$ in general settings. Some, but not all of these numbers are known to be Pisot numbers or Salem numbers[13]. In what follows, these will be referred to as the “beta golden means”, since all of the ones that appear here have explicit origins with the beta shift.

5.2 Counting Orbits

How many trouble spots are there? The table below shows the count M_n of the number of “new” trouble spots, as a function of the midpoint index n .

n	2	3	4	5	6	7	8	9	10	11	12
M_n	1	2	3	6	9	18	30	56	99	186	335

This appears to be Sloane's OEIS A001037 which has a number of known relationships to roots of unity, Lyndon words, and the number of orbits in the tent map. The trouble spots are the positive real roots of polynomials of the form

$$p_{\{b_k\}}(\beta) = \beta^n - \beta^{n-1} - b_1\beta^{n-2} - b_2\beta^{n-3} - \cdots - 1 = 0$$

with the $\{b_k\}$ being certain binary bit sequences. There is just one such (positive, real) root for each such polynomial. These polynomials are relatively prime, in the sense that a bit-sequence b_k is disallowed if it has the same root as some lower-order polynomial. For example, $\beta^4 - \beta^3 - \beta - 1$ is disallowed; it has the same root as $\beta^2 - \beta - 1$. Equivalently, the quadratic is a factor of the quartic; the quartic is not relatively prime with respect to the quadratic.

Although the digits b_k must be zero or one, this definition of irreducibility, plus the counting, suggests some relationship to the irreducible polynomials over the field \mathbb{F}_2 , as that is what the definition of OEIS A001037 counts. Yet the relationship, if any, is quite unclear.³

The values of M_n are given explicitly by Moreau's necklace-counting function

$$M_n = \frac{1}{n} \sum_{d|n} 2^d \mu\left(\frac{n}{d}\right)$$

where the sum runs over all integers d that divide n and μ is the Möbius function. The generating function is

$$\frac{t}{\frac{1}{2} - t} = \sum_{n=1}^{\infty} n M_n \frac{t^n}{1 - t^n}$$

which has a radius of convergence of $|t| < 1/2$. For large n , the asymptotic behavior can be trivially deduced from the defining sum:

$$M_n = \frac{2^n}{n} - \mathcal{O}\left(\frac{2^{n/2}}{n}\right)$$

The above counting function is for necklaces with only two colors. In general, one can have necklaces with 3 or more colors; can that happen here? Yes, of course: if one considers the general β -transform for $2 < \beta$, then, in general, it can be taken as a "kneading transform" with $\lceil \beta \rceil$ branches or folds in it. The analogous trouble-spots again appear, and they can appear after an arbitrary finite-length orbit. Insofar as they correspond to periodic orbits, they are necessarily counted by the necklace-counting function. That is, one must consider all possible strings of $\lceil \beta \rceil$ letters, modulo a cyclic permutation: this is the very definition of a necklace (or "circular word"). The number of such necklaces is given by the necklace-counting function. Each such orbit

³A hypothesis presented in a later section suggests that each orbit should be thought of as a Galois group, with the length of the orbit corresponding to the number of elements in the Galois group. It seems that this might explain much of the structure.

is necessarily represented by a Lyndon word, which is a representative of the conjugacy class of the orbit.

The isomorphism of different systems described by necklace polynomials is a subject that gets some fair amount of attention. Golomb gives an isomorphism between the irreducible polynomials over \mathbb{F}_p , for p prime and necklaces built from Lyndon words.[36, 37] A number of other results exist, including [38, 39]. At any rate, a closer study of the polynomials seems to be called for.

5.3 β -Golden Polynomials

The “trouble spots” occur whenever the k ’th iterate $m_k = T_\beta^k(m_0)$ lands on the starting midpoint $m_k = m_0$. Because of the piece-wise linear form of T_β , the k ’th iterate will be a piece-wise collection of polynomials, each of order k , and of the form $p_{\{b_k\}}(\beta)$. These must be arranged in the manner such that $p_{\{b_k\}}(\beta) = 0$ at each discontinuity, as illustrated in figure 23. This limits the polynomials that can appear; it limits the possible coefficients $\{b_k\}$; not all bit-sequences appear.

The table below explicitly shows the polynomials for the first few orders. A polynomial is included in the table if it is an iterate of a previous polynomial, and if its real root is bracketed by the roots of the earlier iterates. Adopting an ordinal numbering, $p_n(\beta)$ must have the form

$$p_n(\beta) = \begin{cases} \beta(p_{n/2}(\beta) + 1) - 1 & \text{for } n \text{ even} \\ \beta p_{(n-1)/2}(\beta) - 1 & \text{for } n \text{ odd} \end{cases}$$

The roots must be bracketed by the roots of polynomials occurring earlier in the sequence; if the root is not bracketed, then the corresponding polynomial does not appear in the list.

The bracketing relationship is rather awkwardly expressed in the following pseudo-code. Here, r_n is the root $p_n(r_n) = 0$. The polynomial p_n is included in the list if it is the case that this pseudo-code does not fail:

```

mprev := n
m := ⌊n/2⌋
while (0 < m)
    mprev is even and rm < rn then fail
    mprev := m
    m := ⌊m/2⌋

```

The above is a rather awkward way of stating that roots must be bracketed by pairs of previous roots. It can perhaps be more easily understood by studying the location of the discontinuities in figure 23: new discontinuities at higher orders must occur before earlier ones.

Thus, for example, the polynomial $\beta^3 - \beta - 1$ is excluded from the list simply because it is not an iterate of an earlier polynomial, even though it has the interesting real root $1.324717957244746\dots$, the “silver constant”. The numbering scheme does not even have a way of numbering this particular polynomial. Despite this, the silver

constant does appear, but a bit later, as the root of $p_8 = \beta^5 - \beta^4 - 1$, which is an allowed polynomial.

The polynomial $p_5 = \beta^4 - \beta^3 - \beta - 1$ is excluded because it has $\varphi = 1.618\cdots$ as a root, which was previously observed by p_1 . The polynomial $p_9 = \beta^5 - \beta^4 - \beta - 1$ is excluded because its root, $r_9 = 1.497094048762796\cdots$ is greater than its predecessor r_2 ; the recursive algorithm does not compare to r_4 . Note that p_9 is relatively prime to the earlier polynomials, so irreducibility is not a sufficient criterion.

There are other ways to start the table, and to index the polynomials. The given indexing has the property that $2n + 1$, taken as binary, encodes the coefficients of the polynomial. The order of the polynomial is $\lceil \log_2(2n + 1) \rceil$. The index n itself encodes the orbit of the midpoint. That is, writing $n = b_0b_1b_2\cdots b_p$ for binary digits b_k , then $T_\beta^k(\beta/2) < 1/2$ if and only if $b_k = 0$. Note that $b_0 = 1$ always corresponds to $1/2 < \beta/2$ always. By convention, the last digit is always 1, also.

order	$p_n(\beta)$	n	binary	root
0	1			
1	β		0	0
	$\beta - 1$	0	1	1
2	$\beta^2 - \beta - 1$	1	11	$\varphi = \frac{1+\sqrt{5}}{2} = 1.618\cdots$
3	$\beta^3 - \beta^2 - 1$	2	101	1.465571231876768\cdots
	$\beta^3 - \beta^2 - \beta - 1$	3	111	1.839286755214161\cdots
4	$\beta^4 - \beta^3 - 1$	4	1001	1.380277569097613\cdots
	$\beta^4 - \beta^3 - \beta^2 - 1$	6	1101	1.7548776662466924\cdots
	$\beta^4 - \beta^3 - \beta^2 - \beta - 1$	7	1111	1.9275619754829252\cdots
5	$\beta^5 - \beta^4 - 1$	8	10001	1.324717957244746\cdots
	$\beta^5 - \beta^4 - \beta^2 - 1$	10	10101	1.5701473121960547\cdots
	$\beta^5 - \beta^4 - \beta^3 - 1$	12	11001	1.704902776041646\cdots
	$\beta^5 - \beta^4 - \beta^3 - \beta - 1$	13	11011	1.812403619268042\cdots
	$\beta^5 - \beta^4 - \beta^3 - \beta^2 - 1$	14	11101	1.888518845484414\cdots
	$\beta^5 - \beta^4 - \beta^3 - \beta^2 - \beta - 1$	15	11111	1.965948236645485\cdots

The next table lists the acceptable polynomials for order 5, 6 and 7. Again, the coefficients appearing in the polynomial are encoded by the binary value of $2n + 1$ in the sequence. This sequence is not currently known to OEIS.

order	sequence
5	8,10,12,13,14,15
6	16,20,24,25,26,28,29,30,31
7	32,36,40,42,44,48,49,50,52,53,54,56,57,58,59,60,61,62,63

Although there are as many of these polynomials as there are Lyndon words, there is no obvious way to write a bijection between the two. It is almost possible to do so by writing $2n$ in binary, and then reversing the order of the bits, left-to-right. One almost gets the Lyndon words in the correct order, except “in the middle”: so, for example, in the table above, one can get the Lyndon order by exchanging 10 with 12, and 13 with 14. But the table above cannot be re-ordered: the given ordering encodes the orbit of

the midpoint. Apparently, although a given orbit can be cyclically rotated to obtain a Lyndon word, the initial segment of the orbit is not a Lyndon word itself.

Although the necklace polynomial also describes the number of elements of length n in a Hall set, there is no obvious correspondence. That is, if one writes down the Hall set in two generators, one does not obtain the binary strings given in the table above.

Questions that present themselves include:

- Is there a generating function for the sequence of allowed values of n ? What is it?
- How long is the initial segment of each periodic orbit, before the orbit attains its Lyndon word form? What are the values of β where the initial orbits are not in Lyndon form?

5.4 Distribution of β -Golden Roots

The location and distribution of the roots can be visualized in several ways. One direct technique is via the normalization of the Parry-Gelfond measure. The function in eqn 10 or more generally 20 can be integrated in a straight-forward manner. One has

$$I(\beta; z) = \int_0^1 v_{\beta;z}(x) dx = \sum_{n=0}^{\infty} \frac{z^n}{\beta^n} \int_0^1 d_n(x) dx = \sum_{n=0}^{\infty} \frac{z^n}{\beta^n} T^n \left(\frac{\beta}{2} \right)$$

The result is a sawtooth, shown in figure 24. Each discontinuity corresponds to the real root of one of the polynomials. The first few are labelled by the integer labels from the previous table. The labels follow an obvious doubling sequence. Each doubling sequence has a leader. The leaders appear to form a sequence 1,3,7,10,13,15,25,29,31,... The leaders are easily obtained: they are what's left of the earlier polynomial-labelling sequence, after knocking out power-of-two sequences. This sequence is not currently known to OEIS. The leaders above 1 follow a simple pattern: they are always at $2n+1$ of the previous dominant spike. So, for example, the first leader above 6 is 13. The leaders below 1 are given by $n(2n+1)$, so for example, the leader above 16 is $16 \times 33 = 528$.

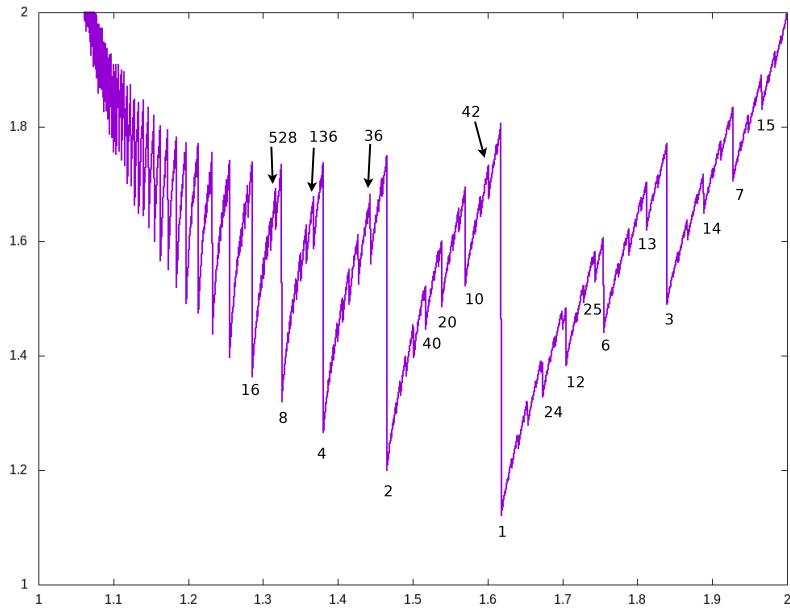

It seems natural to assume that the real roots have some distribution. This seems not to be the case. Figure 25 shows the numerically computed (bin-counted) distribution of the zeros of $p_n(\beta)$ for $n < 2^k$ for three different values of k . This suggests that, in the limit of $k \rightarrow \infty$, almost all $p_n(\beta)$ have roots that approach 2. Although the roots appear to be dense in $1 < \beta < 2$, essentially all of the weight of that density is at 2. Since the roots are countable, the density clearly becomes very thin.

The local distribution of roots can be sensed from the figure 26, which visualizes the distance between neighboring roots.

5.5 Complex Roots

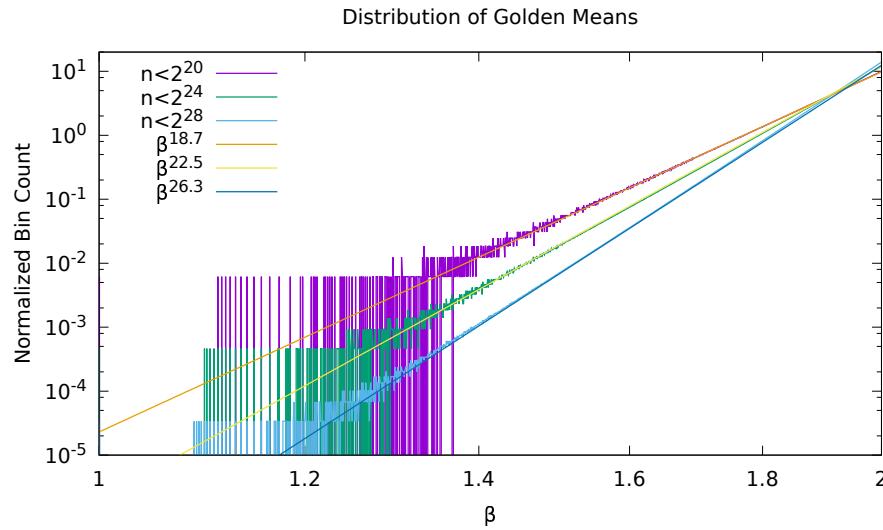

What are the complex roots? Numerical work clearly indicates that they seem to be approximately cyclotomic in some sense or another. They seem to be more-or-less uniformly distributed in an approximate circle, always. The modulus of most of the complex roots appear to be less than one. This is violated for the complex roots of

Figure 24: Normalization Integral

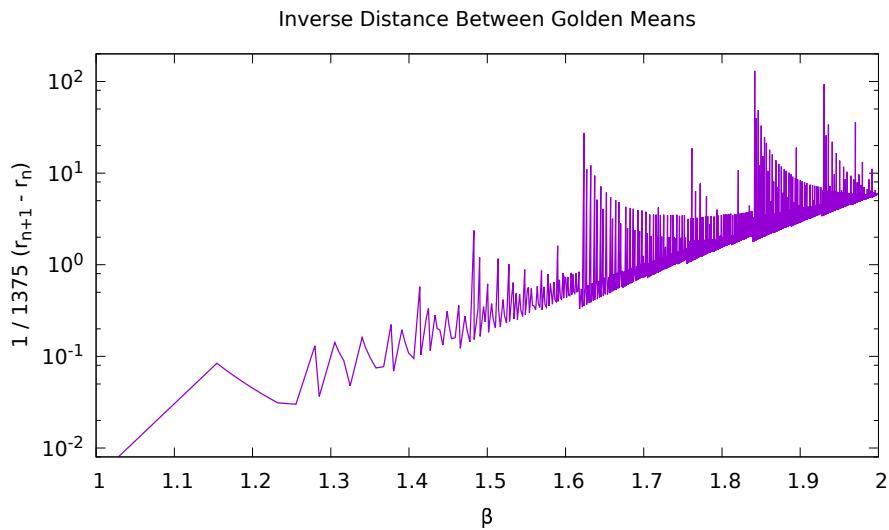

This figure shows the integral $I(\beta) = \sum_{n=0}^{\infty} \beta^{-n} T^n\left(\frac{\beta}{2}\right)$ with $1 < \beta \leq 2$ running along the horizontal axis. Each discontinuity corresponds to the location of a real root of one of the β -Golden polynomials. Some of these are manually labelled by integers, corresponding to the polynomial labels from the previous polynomial table.

Figure 25: Distribution of Golden Means

The bin-counted distribution of roots of $p_n(\beta)$ for three different cutoffs, and the corresponding eyeballed fit. Bin-counting proceeds by dividing the range $1 < \beta < 2$ into 1303 equal-width bins. Proceeding methodically to find roots for all $n < 2^k$ for fixed k , each root is assigned to a bin. At the end of the counting process, the bin-counts are normalized by the width of the bin, and the total number of roots observed (*i.e.* by the Moreau counting function). For fixed k , the distribution appears to be approximately exponential (but not quite - there is a deviation from linearity in the graph above, just barely discernable by naked eye). Three different k 's are shown, and three eyeballed fits. The general trend appears to be that, for fixed k , the distribution is approximately β^α with $\alpha \simeq k + 3 - \log_2 k \simeq \log_2 M_{k+3}$. Clearly, the $k \rightarrow \infty$ limit accumulates all the measure at $\beta = 2$.

Figure 26: Distance Between Means

This figure visualizes the inverse distance between golden means. A total of $1375 = \sum_{k=1}^{12} M_k$ roots were obtained, and then sorted into ascending order. Letting r_n represent the n 'th root in this sequence, this shows the reciprocal distance $1/1375 (r_{n+1} - r_n)$. Increasing the number of roots essentially just rescales this graph, making it progressively more vertical. In essence, almost all of the roots accumulate near $\beta = 2$; roots become increasingly rare the smaller the β . In the limit, one might say that essentially all roots are at $\beta = 2$: although the roots are dense in the interval $1 < \beta < 2$, the counting measure indicates that they are accumulating at $\beta = 2$ only.

$p_{2^k}(\beta) = \beta^{k+2} - \beta^{k+1} - 1$, where some of the roots in the right-hand quadrant have a modulus larger than one. By contrast, the complex roots of $p_{2^k-1}(\beta) = \beta^{k+1} - \sum_{j=0}^k \beta^j$ seem to always have a modulus less than one. These two seem to be the extreme cases: in general, the polynomials appear to be “approximately cyclotomic”. It’s not clear how to make this statement more precise.

These numerical results can be argued heuristically: just divide the polynomial by its leading order. That is, a general polynomial of this form is

$$p_n(z) = z^{k+1} - \sum_{j=0}^k b_j z^{k-j}$$

with the convention that $b_0 = b_k = 1$, and the bit-sequence $n = b_0 b_1 b_2 \cdots b_p$ corresponding to a terminating orbit. Dividing by z^{k+1} gives a series

$$1 - \frac{1}{z} - \frac{b_1}{z^2} - \frac{b_2}{z^3} - \dots$$

Clearly, this can have a zero only when $|z| < 2$ as otherwise, the terms get too small too quickly.

5.6 β -Golden β -Fibonacci Sequences

It is well known that the golden ratio occurs as limit of the ratio of adjacent Fibonacci numbers:

$$\varphi = \lim_{m \rightarrow \infty} \frac{F_m}{F_{m-1}}$$

where $F_m = F_{m-1} + F_{m-2}$. There is a generalization of this, which also has received attention: the tribonacci, quadronacci, etc. sequences, whose limits are

$$\alpha_n = \lim_{m \rightarrow \infty} \frac{F_m^{(n)}}{F_{m-1}^{(n)}}$$

where $F_m^{(n)} = F_{m-1}^{(n)} + F_{m-2}^{(n)} + \cdots + F_{m-n}^{(n)}$.

Is it possible that the real roots of the polynomials $p_n(\beta)$ are also the roots of such sequences? But of course they are! Given a finite string of binary digits $\{b\} = b_0, b_1, \dots, b_k$, write the beta-Fibonacci sequence as

$$F_m^{\{b\}} = b_0 F_{m-1}^{\{b\}} + b_1 F_{m-2}^{\{b\}} + \cdots + b_k F_{m-k}^{\{b\}}$$

The name “beta-Fibonacci” is needed because the term “generalized Fibonacci sequence” is already in wide circulation for the special case of all bits being one. The ratio of successive terms is

$$\alpha^{\{b\}} = \lim_{m \rightarrow \infty} \frac{F_m^{\{b\}}}{F_{m-1}^{\{b\}}}$$

and is given as the (positive) real root of the polynomial

$$p_n(\beta) = \beta^{k+1} - b_0 \beta^k - b_1 \beta^{k-1} - \cdots - b_k = 0$$

These polynomials and their roots were already enumerated and tabulated in the previous section.

The beta-Fibonacci sequences do not appear by accident: these sequences have an ordinary generating function (OGF) given by the polynomial! That is,

$$\sum_{m=0}^{\infty} z^m F_m^{\{b\}} = \frac{z^k}{1 - b_0 z - b_1 z^2 - \cdots - b_k z^{k+1}} = \frac{1}{zp_n\left(\frac{1}{z}\right)}$$

The factor of z^k in the numerator serves only to initiate the sequence so that $F_0^{\{b\}} = \cdots = F_{k-1}^{\{b\}} = 0$ and $F_k^{\{b\}} = 1$.

These sequences are generic: they indicate how many different ways one can partition the integer m into elements of the set $\{b_0, 2b_1, 3b_2, \dots, (k+1)b_k\}$. So, for example, the entry for $n = 12$ in the table below corresponds to OEIS A079971, which describes the number of ways an integer m can be partitioned into 1, 2 and 5 (or that $5m$ can be partitioned into nickels, dimes and quarters). This corresponds to the bit sequence $\{b\} = 11001$; that is, $\{b_0, 2b_1, 3b_2, \dots, (k+1)b_k\} = \{1 \cdot 1, 2 \cdot 1, 3 \cdot 0, 4 \cdot 0, 5 \cdot 1\} = \{1, 2, 5\}$. From such partitions, it appears that one can build partitions of the positive integers that are disjoint, and whose union is the positive integers. This suggests a question: can these partitions be expressed as Beatty sequences?

The previous table is partly repeated below, this time annotated with the OEIS sequence references.

n	binary	root	root identity	sequence
0	1	1		
1	11	$\varphi = \frac{1+\sqrt{5}}{2} = 1.618\dots$	golden ratio	Fibonacci A000045
2	101	1.465571231876768\dots	OEIS A092526	Narayana A000930
3	111	1.839286755214161\dots	tribonacci A058265	tribonacci A000073
4	1001	1.380277569097613\dots	2nd pisot A086106	A003269
6	1101	1.754877666246692\dots	OEIS A109134	A060945
7	1111	1.927561975482925\dots	tetranacci A086088	tetranacci A000078
8	10001	1.324717957244746\dots	silver A060006	A003520
10	10101	1.570147312196054\dots	pisot A293506	A060961
12	11001	1.704902776041646\dots		A079971
13	11011	1.812403619268042\dots		A079976
14	11101	1.888518845484414\dots		A079975
15	11111	1.965948236645485\dots	pentanacci A103814	A001591

All of these integer sequences and roots participate in a number of curious relations having a regular form; this is, of course, the whole point of listing them in the OEIS. This suggests a question: do the known relationships generalize to the beta-shift setting?

For example, there are various known relations for the “generalized golden means”. These are the roots of the series for which all $b_k = 1$, that is, the roots of

$$\beta^{k+1} - \beta^k - \beta^{k-1} - \cdots - 1 = 0$$

In the present notation, these would be the roots of the polynomials $p_n(\beta) = 0$ for $n = 2^k - 1$. Such roots can be rapidly computed by a series provided by Hare, Prodinger and Shallit[34]:

$$\frac{1}{\alpha_k} = \frac{1}{2} + \frac{1}{2} \sum_{j=1}^{\infty} \frac{1}{j} \binom{j(k+1)}{j-1} \frac{1}{2^{j(k+1)}}$$

This series is obtained by making good use of the Lagrange inversion formula. Here, α_k is the k 'th generalized golden mean, i.e. the solution $p_{2^k-1}(\alpha_k) = 0$. Can the Hare series be extended to provide the roots r_n of $p_n(r_n) = 0$ for general n ?

Another set of observations seem to invoke the theory of complex multiplication on elliptic curves, and pose additional questions. So:

The tribonacci root r_3 is given by

$$r_3 = \frac{1}{3} \left(1 + \sqrt[3]{19 + 3\sqrt{33}} + \sqrt[3]{19 - 3\sqrt{33}} \right) \simeq 1.839 \dots$$

The silver number (plastic number) r_8 is given by

$$r_8 = \frac{1}{6} \left(\sqrt[3]{108 + 12\sqrt{69}} + \sqrt[3]{108 - 12\sqrt{69}} \right) \simeq 1.324 \dots$$

The Narayana's cows number r_2 is given by

$$r_2 = \frac{1}{6} \sqrt[3]{116 + 12\sqrt{93}} + \frac{2}{3\sqrt[3]{116 + 12\sqrt{93}}} + \frac{1}{3} \simeq 1.645 \dots$$

The root r_6 is related to the silver number r_8 as $r_8 = r_6(r_6 - 1)$ and is given by

$$r_6 = \frac{1}{6} \sqrt[3]{108 + 12\sqrt{69}} + \frac{2}{\left(\sqrt[3]{108 + 12\sqrt{69}} \right)^2} \simeq 1.754 \dots$$

Do the other roots have comparable expressions? To obtain them, is it sufficient to articulate the theory of “complex multiplication” on elliptic curves? The appearance of only the cube and square roots is certainly suggestive of an underlying process of points on elliptic curves.

5.7 β -Fibonacci sequences as shifts

The nature of the β -Fibonacci sequences as shift sequences can be emphasized by noting that they arise from the iteration of a $(k+1) \times (k+1)$ matrix in lower-Hessenberg form:

$$B = \begin{bmatrix} b_0 & 1 & 0 & 0 & \cdots & 0 \\ b_1 & 0 & 1 & 0 & \cdots & 0 \\ b_2 & 0 & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & & \ddots & \vdots \\ b_{k-1} & 0 & 0 & 0 & \cdots & 1 \\ b_k & 0 & 0 & 0 & \cdots & 0 \end{bmatrix} \quad (27)$$

That is, the m 'th element of the sequence is obtained from the m 'th iterate B^m . That such iteration results in integer sequences has long been observed in the theory of continued fractions. It's useful to work an explicit example. For the golden ratio, one has

$$B = \begin{bmatrix} 1 & 1 \\ 1 & 0 \end{bmatrix}$$

and the iterates are

$$B^2 = \begin{bmatrix} 2 & 1 \\ 1 & 1 \end{bmatrix}, B^3 = \begin{bmatrix} 3 & 2 \\ 2 & 1 \end{bmatrix}, B^4 = \begin{bmatrix} 5 & 3 \\ 3 & 2 \end{bmatrix}, B^n = \begin{bmatrix} F_n & F_{n-1} \\ F_{n-1} & F_{n-2} \end{bmatrix}$$

with F_n being the n 'th Fibonacci number, as usual. For the general case, one has that

$$B^m = \begin{bmatrix} F_m^{\{b\}} & F_{m-1}^{\{b\}} & F_{m-2}^{\{b\}} & \cdots & F_{m-k+1}^{\{b\}} & F_{m-k}^{\{b\}} \\ F_{m-1}^{\{b\}} & F_{m-2}^{\{b\}} & F_{m-3}^{\{b\}} & \cdots & F_{m-k}^{\{b\}} & F_{m-k-1}^{\{b\}} \\ F_{m-2}^{\{b\}} & F_{m-3}^{\{b\}} & & \cdots & & \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ F_{m-k+1}^{\{b\}} & & \cdots & & & \\ F_{m-k}^{\{b\}} & & \cdots & & & F_{m-2k}^{\{b\}} \end{bmatrix}$$

so that the top row consists of the latest sequence values. When multiplied by the bits, this just generates the next iterate in the sequence. The upper-diagonal 1's just serve to shift columns over by one, with each iteration: that is why it's a shift!

The characteristic polynomial of this matrix is, of course, the polynomial p_n :

$$\det[B - xI] = (-1)^k p_n(x)$$

Thus, we can trivially conclude that the eigenvalues of B are given by the roots of $p_n(x)$. This matrix is in lower-Hessenberg form; this makes it obvious that it's a shift; a finite shift, in this case.

5.8 Equivalent labels for orbits

At this point, it should be clear that there are several equivalent ways of labeling the expressions under consideration. These are recapped here. Proofs are omitted; they are straight-forward.

5.8.1 Orbits

For every given $1 < \beta < 2$ there is a unique orbit of midpoints $\{m_p\}$ given by $m_p = T_\beta(m_{p-1}) = T_\beta^p(m_0)$ and $m_0 = \beta/2$. The orbits are in one-to-one correspondence with β . The midpoints are the same as the Renyi-Parry sequence; namely $T_\beta^p(\beta/2) = (\beta/2)t_\beta^p(1)$, recalling here the notation of eqn 8 and 10.

5.8.2 Orbit encoding

The midpoint generates a unique sequence of bits $\{b_0, b_1, \dots, b_k, \dots\}$ given by the left-right moves of the mid-point, as it is iterated. That is, $b_k = \Theta(m_k - 1/2)$ so that b_k is one if the midpoint is greater than half, else b_k is zero. Each bit-sequence is in one-to-one correspondence with β .

5.8.3 Monotonicity

The compressor function $w(\beta) = \sum_k b_k 2^{-k}$ is a monotonically increasing function of β , so that values of $w(\beta)$ are in one-to-one correspondence with β .

5.8.4 Polynomial numbering

If the orbit is periodic, then there exists a polynomial $p_n(z) = z^{k+1} - b_0 z^k - b_1 z^{k-1} - \dots - b_{k-1} z - 1$ with $k = 1 + \lfloor \log_2 n \rfloor$ being the length of the orbit. The positive real root of $p_n(z)$ is β . The integer n is in one-to-one correspondence with the bit sequence, and with the value of β . The integer is explicitly given by $2n + 1 = \sum_{j=0}^k 2^j b_j$.

5.8.5 Odometer

If the orbit is periodic, then there exists a finite-length integer sequence $[m_1, m_2, \dots, m_k]$ whose value

$$n = [m_1, m_2, \dots, m_k] = 2^{m_k + m_1 + m_2 + \dots + m_{k-2}} (2[m_1, m_2, \dots, m_{k-1}] + 1)$$

corresponds to the bit sequence $\{b\} = b_0, b_1, \dots, b_k$ via the integer $2n + 1 = \sum_{j=0}^k 2^j b_j$.

5.8.6 Integer sequences

If the orbit is periodic, then there exists a sequence of integers $F^{\{b\}}$, the beta-Fibonacci sequence, that is in one-to-one correspondence with the finite bit sequence $\{b\} = b_0, b_1, \dots, b_k$, and with the value of β .

5.8.7 Shift matrix

If the orbit is periodic, then the finite bit sequence $\{b\} = b_0, b_1, \dots, b_k$ defines a lower-Hessenberg “golden shift” matrix B , as shown in eqn 27.

5.8.8 Summary

To summarize: any one of these: the integer n , the polynomial $p_n(x)$, the integer sequence $F_m^{\{b\}}$, the orbit of midpoints $m_p = T^p(\beta/2)$, the orbit encoding $\{b\}$, the shift matrix B , the value of the compressor function $w(\beta)$ and, of course, β itself can each be used as a stand-in for the others. Specifying one determines the others; they all uniquely map to one-another. They are all equivalent labels. Fashionably abusing notation, $n \equiv p_n(x) \equiv \{b\} \equiv F_m^{\{b\}} \equiv m_p \equiv w(\beta) \equiv \beta \equiv B$.

An explicit expression relating the orbit encoding and the orbit can be read off directly from eqn 7. Plugging in,

$$m_p = T_\beta^{p+1} \left(\frac{\beta}{2} \right) = \frac{\beta}{2} \left[\beta^{p+1} - \sum_{j=0}^p b_j \beta^{p-j} \right] \quad (28)$$

for $p < k$ the length of the bit sequence, and $m_k = T_\beta^{k+1}(\beta/2) = \beta p_n(\beta)/2 = 0$ terminating, since β is the positive root of $p_n(x)$.

Four of the correspondences given above ask for periodic orbits. Three of these can be extended to non-periodic orbits in an unambiguous and uncontroversial way. The extensions are covered in the next two sections. The fourth is the numbering n of the finite orbits. These are countable; there is no way to extend the counting number n to the non-periodic orbits. Ineed, there ae too many: the non-periodic orbits are uncountable.

5.9 Infinite-nacci integer sequences

The beta-Fibonacci integer sequence can be extended to arbitrary (*viz.* infinite) length bit sequences, as

$$F_m^{\{b\}} = \sum_{j=1}^m b_{j-1} F_{m-j}^{\{b\}}$$

starting with $F_0^{\{b\}} = 1$. The sum is always finite, but one cannot perform it without first knowing at least the first m bits of the (now infinite) bit-sequence $\{b\}$. The integer sequence still has the desirable property it had before:

$$\beta = \lim_{m \rightarrow \infty} \frac{F_m^{\{b\}}}{F_{m-1}^{\{b\}}}$$

Here, the β value is the one associated to $\{b\}$. So, as before, the real number β and the bit sequence $\{b\}$ label exactly the same orbit.

Remarkably, one can be sloppy in how one deals with periodic orbits with this extention. One has two choices that are equivalent: One choice is to truncate, so that the bit-sequence ends with all-zeros, effectively rendering it of finite length. The alternative is to allow it to continue periodically, forever. Either form results in the same β -Fibonacci sequence!

As an example, consider $\beta = 1.6$, which is close to the golden ratio, but not quite. It has an infinite non-periodic (non-recurring) bit-sequence $\{b\} = 101010010100101000000100\dots$. The generated integer sequence is $F_m^{\{b\}} = 1, 1, 1, 2, 3, 5, 8, 12, 20, 32, 51, 82, 130, 209, 335, 535, \dots$ which undershoots the Fibonacci sequence (12 appears, where we expected 13, and 20 instead of 21, and so on). The ratio of the last two is $535/335 = 1.597\dots$ and the previous is $335/209 = 1.603\dots$ and the ratio of successive elements eventually converges to 1.6. By comparison, the Fibonacci sequence is generated by the bit-string 10101010... of alternating ones and zeros.

The β -Fibonacci representation of the orbits has the remarkable property that one does not need some *a priori* mechanism to know if some orbit is periodic or not. This

dual-representation of periodic orbits is reminiscent of a property commonly seen in Cantor space 2^ω representations of the real number line, where the dyadic rationals (which are countable, of course) map to two distinct bit-sequences (one ending in all-ones, the other ending in all-zeros). A more general setting for this is given in symbolic dynamics, where the totally disconnected Bernoulli scheme N^ω can be used to represent elements of certain countable sets two different ways. For $N = 10$, one famously has that $1.000\dots = 0.999\dots$ as an example. So likewise here, one can toggle between finite and infinite-periodic strings. So, given a finite string $\{b\} = b_0, b_1, \dots, b_{k-1}, b_k$ which has, by definition, $b_k = 1$, create a new finite string that is twice as long: $\{b'\} = b_0, b_1, \dots, b_{k-1}, 0, b_0, b_1, \dots, b_k$ which necessarily has exactly the same beta-Fiboanacci sequence. That is, $F_m^{\{b'\}} = F_m^{\{b\}}$. Once can repeat this process *ad infinitum*, obtaining an infinite periodic string. The difference between these two is simply the difference between a less-than-sign, and a less-than-or-equal sign used in the generation of the orbit, as noted at the very beginning of this chapter. We have proven: finite orbits are exactly the same as infinite periodic orbits, at least when represented by real numbers and by integer sequences. Conversely, the difference between using $<$ and \leq during iteration is immaterial for describing convergents.

5.10 Infinite β -Polynomials

An infinite polynomial is, of course, an analytic function. The goal here is to extend the finite framework. The definition of the polynomials above requires a finite bit sequence. This can be extended to an asymptotic series, by writing first

$$p_n(z) = z^{k+1} \left(1 - b_0 z^{-1} - b_1 z^{-2} - \dots - b_k z^{-k-1} \right)$$

Set $\zeta = 1/z$ to get

$$\zeta^{k+1} p_n \left(\frac{1}{\zeta} \right) = 1 - b_0 \zeta - b_1 \zeta^2 - \dots - b_k \zeta^{k+1}$$

which extends to the holomorphic function

$$q^{\{b\}}(\zeta) = 1 - \sum_{j=0}^{\infty} b_j \zeta^{j+1}$$

This is manifestly holomorphic on the unit disk, as each coefficient is either zero or one. It has a positive real zero, of course: $q^{\{b\}}(1/\beta) = 0$. Comparing to eqn 22, we see that this is exactly the same function, or rather, it's negative. Indeed, following the definition, $b_n = d_n(1/2)$ and so $E(\beta; \zeta) = -q^{\{b\}}(\zeta)$.

This at last provides a foot in the door for correctly describing the eigenvalues of the β -transfer operator: they are in one-to-one correspondence with the zeros of $q^{\{b\}}(\zeta)$. As before, though, this only exposes a discrete spectrum in the region $1/\beta < |\lambda| \leq 1$; if there is any spectrum outside this region, the methods here cannot access it.

5.11 β -Hessenberg operator

Extending the golden shift matrix B of eqn 27 to an infinite-dimensional operator is a bit trickier. Of course, one could just declare the matrix elements of the operator to be this-and-such, but these matrix elements are with respect to what basis? Is the operator even bounded? The answer to the second question is obviously “no”.

The characteristic equation of B is $\det(B - \lambda I) = p_n(\lambda) = 0$; the Frobenius-Perron eigenvalue $\beta > 1$ is too large, although the $k - 1 = \lfloor \log_2 n \rfloor$ other roots are conveniently arranged near the unit circle, more-or-less equidistant from one another. The solution is to rescale B by $1/\beta$. The Frobenius-Perron eigenvalue is now one, and the remaining eigenvalues distributed near or on a circle of radius $1/\beta$. We may as well take the transpose as well, so that $\mathcal{H}_\beta = B^T/\beta$ is in upper-Hessenberg form. Rescaled in this way, it now seems safe to declare, by fiat, that the operator \mathcal{H}_β is the correct extension of the matrix B to infinite dimensions. Just to be explicit: given the bit-sequence $\{b\}$, the operator \mathcal{H}_β has the matrix elements

$$\begin{aligned}\langle 0 | \mathcal{H}_\beta | j \rangle &= \frac{b_j}{\beta} \\ \langle j+1 | \mathcal{H}_\beta | j \rangle &= \frac{1}{\beta}\end{aligned}$$

with all other entries being zero. This is clearly in upper-Hessenberg form, with the subdiagonal providing the shift.

Comparing to the upper-Hessenberg form of \mathcal{L}_β of eqn 25, and the numerical results on its eigenvalues, it seems clear that \mathcal{H}_β and \mathcal{L}_β must surely be similar. That is, there must be an operator S such that

$$\mathcal{L}_\beta = S^{-1} \mathcal{H}_\beta S$$

The invariant measure $\mathcal{L}_\beta \rho = \rho$ is mapped to $\sigma = S\rho$, where $\mathcal{H}_\beta \sigma = \sigma$ is the FP-eigenvector. It is easy to write down σ explicitly: $\sigma = (1, \beta^{-1}, \beta^{-2}, \dots)$, that is, $\sigma_j = \beta^{-j}$. This is obviously so: the subdiagonal entries of \mathcal{B}_β act as a shift on σ and the top row is just

$$1 = \sum_{j=0}^{\infty} \langle 0 | \mathcal{H}_\beta | j \rangle \sigma_j = \sum_{j=0}^{\infty} b_j \beta^{-j-1} = 1 - q^{\{b\}} \left(\frac{1}{\beta} \right) = 1$$

Although \mathcal{H}_β is no more solvable than \mathcal{L}_β in the wavelet basis is, it is certainly much, much easier to work with. It also re-affirms the ansatz 21 for eigenfunctions. To be explicit: if v is a vector satisfying $\mathcal{H}_\beta v = \lambda v$, with vector elements v_j , then the function

$$v(x) = \sum_{j=0}^{\infty} d_j(x) v_j$$

is an eigenfunction of the transfer operator: that is, $[\mathcal{L}_\beta v](x) = \lambda v(x)$, or, explicitly:

$$\frac{1}{\beta} \left[v\left(\frac{x}{\beta}\right) + v\left(\frac{x}{\beta} + \frac{1}{2}\right) \right] \Theta\left(\frac{\beta}{2} - x\right) = \lambda v(x) \quad (29)$$

which is just eqn 16. So, for $\lambda = 1$, this is just $v = \sigma$ which is just eqn 21 for $z = 1$, the invariant measure, as always. But it also says more: the *only* solutions to $\mathcal{H}_\beta v = \lambda v$ are necessarily of the form $v = (1, (\lambda\beta)^{-1}, (\lambda\beta)^{-2}, \dots)$, because the subdiagonal forces this shift. To satisfy the top row of \mathcal{H}_β , one must have that

$$\lambda = \sum_{j=0}^{\infty} \langle 0 | \mathcal{H}_\beta | j \rangle v_j = \frac{1}{\beta} \sum_{j=0}^{\infty} \frac{b_j}{(\lambda\beta)^j} = \lambda \left(1 - q^{\{b\}} \left(\frac{1}{\lambda\beta} \right) \right) = \lambda$$

and so the eigenvalue λ is exactly the eigenvalue that solves the β -series $q^{\{b\}}(1/\lambda\beta) = 0$. This effectively concludes a proof: the solutions to this series are the only eigenvalues of the β -transfer operator; there are no others.

To recap: periodic orbits have an associated shift matrix B ; this extends naturally to a shift operator \mathcal{H}_β for non-periodic orbits. The shift operator has a sufficiently simple form that its eigenvectors can be explicitly written down in closed form; they are necessarily coherent states⁴. The top row of the shift operator defines a holomorphic function $q^{\{b\}}$ whose zeros correspond to eigenstates of the shift operator. The holomorphic function is determined by the binary digit sequence $\{b\}$. The binary digit sequence is obtained from the iterated midpoint, as $b_j = d_j(1/2)$ where $d_j(x) = 1$ if $x < T^n(\beta/2)$. This is enough to prove eqn 29 holds for the special value $x = 0$ (for *any* eigenvalue λ). It was previously proven that the vanishing of $q^{\{b\}}$ is independent of x , *i.e.* that eqn 29 holds for any x .

5.12 Eigenfunctions from periodic orbits

To recap: eigenstates of the transfer operator correspond with the zeros of $q^{\{b\}}(\zeta)$, or, more precisely, the zeros for which $|\zeta| \leq 1$. The reason for this limitation is that the eigenstates are explicitly given by

$$v(x) = \sum_{m=0}^{\infty} d_m(x) \zeta^m$$

for $\zeta = 1/\beta\lambda$; this is absolutely convergent only for $|\zeta| < 1$. One might hope to analytically continue this to the entire complex plane, but the continuation depends on the digit sequence $d_m(x)$. One might expect that an analytic continuation is impossible, as the $d_m(x)$ are ergodic, and thus throws up some kind of essential singularity at $|\zeta| = 1$ that cannot be continued past. We are lacking in tools and language to discuss this situation. Perhaps some insight can be gleaned by examining the periodic orbits...

5.12.1 Case n=1

Consider first $\beta = \varphi = 1.6180\dots$ the golden ratio. The corresponding finite beta-polynomial is $q^{\{11\}}(\zeta) = 1 - \zeta - \zeta^2$; the infinite series is

$$q^{\{1010101\dots\}}(\zeta) = 1 - \zeta - \zeta^3 - \zeta^5 - \dots = (1 - \zeta - \zeta^2) / (1 - \zeta^2)$$

⁴The term “coherent states” comes from quantum optics: a state that can be written as an analytic series over states/vectors expressed in a different basis.

which has a positive real zero at $\zeta = 1/\varphi$ and poles at $\zeta = \pm 1$. The zero corresponds to the FP eigenvalue of one. The invariant measure is

$$v(x) = \sum_{m=0}^{\infty} \frac{d_m(x)}{\varphi^m} = \begin{cases} \varphi & \text{for } 0 \leq x < \frac{1}{2} \\ 1 & \text{for } \frac{1}{2} \leq x < \varphi \\ 0 & \text{for } \varphi \leq x \end{cases}$$

There is a negative real zero at $\zeta = -\varphi$, but the eigenfunction summation is not convergent here.

5.12.2 Case n=2

The $n = 2$ case has the finite bitstring $\{b\} = 101$ and the periodic bitstring $\{b\} = 1001001\dots$. The corresponding finite beta-polynomial is $q^{\{101\}}(\zeta) = 1 - \zeta - \zeta^3$; the infinite series is

$$q^{\{1001\dots\}}(\zeta) = 1 - \zeta - \zeta^4 - \zeta^7 - \dots = (1 - \zeta - \zeta^3) / (1 - \zeta^3)$$

which has a positive real zero at $\zeta = 1/\beta = 0.6823\dots$ and three poles on the unit circle. The FP eigenvalue provides $\beta = 1.4655\dots$. The invariant measure is

$$v(x) = \sum_{m=0}^{\infty} \frac{d_m(x)}{\beta^m} = \begin{cases} \frac{\beta}{\beta-1} & \text{for } 0 \leq x < T\left(\frac{\beta}{2}\right) \\ \frac{1}{\beta-1} & \text{for } T\left(\frac{\beta}{2}\right) \leq x < \frac{1}{2} \\ \frac{1/\beta}{\beta-1} & \text{for } \frac{1}{2} \leq x < \beta \\ 0 & \text{for } \beta \leq x \end{cases}$$

There are many equivalent ways to write the invariant measure; the above just selected some representatives from the coset of equivalent expressions. For example, the third entry could be written as $\beta = 1/\beta(\beta - 1)$.

5.12.3 Case n=3

The $n = 3$ case has the finite bitstring $\{b\} = 111$ and the periodic bitstring $\{b\} = 1101101\dots$. The corresponding finite beta-polynomial is $q^{\{111\}}(\zeta) = 1 - \zeta - \zeta^2 - \zeta^3$; the infinite series is

$$q^{\{110110\dots\}}(\zeta) = 1 - \zeta - \zeta^2 - \zeta^4 - \dots = (1 - \zeta - \zeta^2 - \zeta^3) / (1 - \zeta^3)$$

which has a positive real zero at $\zeta = 1/\beta = 0.5436\dots$ and three poles on the unit circle. The FP eigenvalue gives $\beta = 1.8392\dots$. The invariant measure is

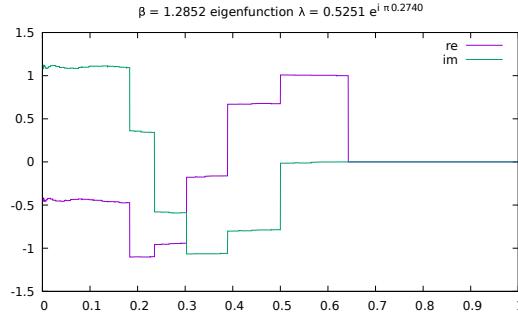

$$v(x) = \begin{cases} \frac{\beta}{\beta-1} & \text{for } 0 \leq x < \frac{1}{2} \\ \beta & \text{for } \frac{1}{2} \leq x < T\left(\frac{\beta}{2}\right) \\ \frac{1}{\beta-1} & \text{for } T\left(\frac{\beta}{2}\right) \leq x < \beta \\ 0 & \text{for } \beta \leq x \end{cases}$$

5.12.4 Case n=4,6,7

The pattern gets repetitive. There is no case $n = 5$, as this is not one of the allowed orbits. The bitstrings are those previously listed in tables; they are $\{b\} = 1001$ $\{b\} = 1101$ and $\{b\} = 1111$. The infinite series is $q^{\{b\}}(\zeta) = q^{\{b\}}(\zeta) / (1 - \zeta^4)$. The zeros are as previously listed. The $n = 4$ plateaus are at $\frac{1}{\beta-1} \left[\beta, 1, \frac{1}{\beta}, \frac{1}{\beta^2} \right]$. The $n = 6$ plateaus are at $\left[\frac{\beta}{\beta-1}, \frac{\beta^2}{(\beta^2-1)(\beta-1)}, \beta, \frac{\beta}{(\beta^2-1)(\beta-1)} \right]$. The $n = 7$ plateaus are at $\left[\frac{\beta}{\beta-1}, \beta, \frac{\beta+1}{\beta(\beta-1)}, \frac{1}{\beta-1} \right]$. Again, the values at the plateaus can be written in many different ways, given the finite polynomail.

5.12.5 Case n=16

The $n = 16$ polynomial is the first one to have complex zeros inside the unit disk. The finite bitstring is $\{b\} = 100001$ and so the polynomial is $q^{\{100001\}}(\zeta) = 1 - \zeta - \zeta^6$. The positive real root is $\zeta = 0.7780895986786\cdots$ and so $\beta = 1/\zeta = 1.28519903324535\cdots$. The complex zeros are located at $\zeta = 0.965709509\cdots \exp \pm i\pi 0.2740452363\cdots$ which corresponds to eigenvalues are $\lambda = 0.525107\cdots \pm i0.611100\cdots = 0.805718\cdots \exp \pm i\pi 0.274045\cdots$. The correspnding eigenfunction is shown immediately below.

The order of $q^{\{b\}}$ is six, and this has six almost-plateaus; they are not quite flat, although they are close to it, presumably because ζ is close to one.

5.12.6 The general case

Generalizing from the above, one finds the following:

- For a period- k orbit, the infinite series is $q^{\{b\}}(\zeta) = q^{\{b\}}(\zeta) / (1 - \zeta^k)$.
- The first label n for which $q^{\{b\}}(\zeta)$ has a complex zero within the disk is $n = 16$. As a general rule, it seems that complex zeros inside the disk only appear for $\beta < \varphi$ (I beleive; have not carefully checked. This seems reasonable, as later chapters show that the region of $\beta < \varphi$ behaves very differently from larger values.)

- The invariant measure has k plateaus. The plateau boundaries are given by $T^m\left(\frac{1}{2}\right)$ for $m = \{0, \dots, k-1\}$ (so that $T^0\left(\frac{1}{2}\right) = \frac{1}{2}$ and $T^1\left(\frac{1}{2}\right) = \frac{\beta}{2}$, and so on).
- The left-most plateau (of the invariant measure) is at $\beta / (\beta - 1) = \sum_{n=0}^{\infty} 1/\beta^n$.
- The other plateaus appear to be at simple rational functions of β , but a precise expression is elusive.

To solve the last issue, perhaps one can find tools in Galois theory. Let $\mathbb{R}[\zeta]$ be the ring of polynomials in ζ and consider the quotient ring $L = \mathbb{R}[\zeta]/q^{\{b\}}(\zeta)$. This L is a field extension of \mathbb{R} and so one expects a Galois group $\text{Gal}(L/\mathbb{R})$. The plateaus of the invariant measure are presumably associated with the group elements. This seems like a promising direction to go in: perhaps this is just enough to explain the length of an orbit, the sequence of points in the orbit, the reason that some polynomials are forbidden (they don't generate prime ideals), the appearance of Moreau's necklace-counting function, etc. This remains an unfinished exercise.

5.13 Factorization

The polynomials factorize. Let r_n denote the real positive root of $p_n(x)$ – that is, $p_n(r_n) = 0$. Then one has the factorizations (dropping the subscript on r for readability)

$$p_1(x) = x^2 - x - 1 = (x - r)(x + r - 1) = (x - r)(x + p_0(r))$$

where $p_0(x) = x - 1$. Likewise, there are two order-3 polynomials. They factor as

$$p_2(x) = x^3 - x - 1 = (x - r)(x^2 + xp_0(r) + rp_0(r))$$

while

$$p_3(x) = x^3 - x^2 - x - 1 = (x - r)(x^2 + xp_0(r) + p_1(r))$$

Continuing in this way, there are three order-4 polynomials. They factor as

$$p_7(x) = x^4 - x^3 - x^2 - x - 1 = (x - r)(x^3 + x^2p_0(r) + xp_1(r) + p_3(r))$$

and

$$p_6(x) = x^4 - x^3 - x^2 - 1 = (x - r)(x^3 + x^2p_0(r) + xp_1(r) + rp_1(r))$$

and (noting that there is no p_5 that occurs in the series)

$$p_4(x) = x^4 - x^3 - 1 = (x - r)(x^3 + x^2p_0(r) + xrp_0(r) + r^2p_0(r))$$

There's clearly a progression, but perhaps a bit difficult to grasp. It can be more clearly seen by writing $p_n = q_{2n+1}$ and then writing out $2n+1$ in binary. So, once again, from the top:

$$p_1(x) = q_{11}(x) = (x - r)(x + q_1)$$

where $q_1 = q_1(r)$ which adopts the shorthand that the q polynomials on the right-hand side always have r as an argument, which can be dropped for clarity. Note also that

$q_0(r) = r$ was already previously observed, in an earlier section. That is, using the dropped- r convention, $q_0 = r$. Next

$$p_2(x) = q_{101}(x) = (x - r)(x^2 + xq_1 + q_{01})$$

where, by definition, $q_{01}(x) \equiv rq_1(x)$. Next,

$$p_3(x) = q_{111}(x) = (x - r)(x^2 + xq_1 + q_{11})$$

is the second factorization of order 3. For order 4, one has

$$p_4(x) = q_{1001}(x) = (x - r)(x^3 + x^2q_1 + xq_{01} + q_{001})$$

where, this time, $q_{001}(x) = xq_{01}(x) = x^2q_1(x)$. Continuing,

$$p_6(x) = q_{1101}(x) = (x - r)(x^3 + x^2q_1 + xq_{11} + q_{011})$$

where, by defintion, $q_{011}(x) \equiv xq_{11}(x)$. Finally,

$$p_7(x) = q_{1111}(x) = (x - r)(x^3 + x^2q_1 + xq_{11} + q_{111})$$

It is worth doing one more, just to clinch that the reversal of the bit sequence is indeed correct. For this purpose, $p_{12} = q_{11001}$ should serve well. One has

$$\begin{aligned} p_{12}(x) &= q_{11001}(x) = (x - r)(x^4 + x^3p_0(r) + x^2p_1(r) + xrp_1(r) + r^2p_1(r)) \\ &= (x - r)(x^4 + x^3q_1 + x^2q_{11} + xq_{011} + q_{0011}) \end{aligned}$$

The general pattern should now be clear. Given one of the admissible bit sequences $b_0b_1b_2\cdots b_{k-1}b_k$ and recalling that $b_k = 1$ always, (and that $b_0 = 1$ always) one has

$$p_n(z) = q_{b_0b_1b_2\cdots b_{k-1}b_k}(z) = z^{k+1} - b_0z^k - b_1z^{k-1} - \cdots - b_{k-1}z - 1$$

which has the factorization, with bits reversed:

$$q_{b_0b_1b_2\cdots b_{k-1}b_k}(z) = (z - r)\left(z^k + z^{k-1}q_{b_0} + z^{k-2}q_{b_1b_0} + z^{k-3}q_{b_2b_1b_0} + \cdots + q_{b_{k-1}b_{k-2}\cdots b_1b_0}\right)$$

where, as already noted, each q is a polynomial in the root r . Although, notionally, the root r was taken as the real root, the above factorization works for any root.

The trick can be repeated. Although at first it might seem daunting, the pattern is uniform: every power of z occurred in the above. Let $s \neq r$ be some other root. Then

$$q_{b_0b_1b_2\cdots b_{k-1}b_k}(z) = (z - r)(z - s)\left(z^{k-1} + (s + q_{b_0})z^{k-2} + (s^2 + sq_{b_0} + q_{b_0b_1})z^{k-3} + \cdots\right)$$

The coefficient of the next term being $s^3 + s^2q_{b_0} + sq_{b_0b_1} + q_{b_0b_1b_2}$ and so on. From this point one, this becomes just an ordinary factorization of polynomials... well, but so was the first step, as well. What made the first step interesting was that, because the coefficients at that step were explicitly either zero or one, the corresponding reversal of the bit sequence became manifest.

One may as well bring this detour to a close. There's nothing particularly magic in the above factorization, other than the combinatorial re-arrangement of the polynomial labels. A generic polynomial factorization looks like the below, for comparison. If

$$p(x) = x^{n+1} + c_0x^n + c_1x^{n-1} + \cdots + c_n$$

and if r is a root of $p(x)$ viz $p(r) = 0$ then

$$\begin{aligned} p(x) &= (x - r)(x^n + (r + c_0)x^{n-1} + (r^2 + c_0r + c_1)x^{n-2} + \cdots) \\ &= (x - r)(x^n + a_0x^{n-1} + a_1x^{n-2} + \cdots) \end{aligned}$$

with

$$a_k = r^{k+1} + \sum_{j=0}^k c_j r^{k-j}$$

There are some notable values occurring in the factorization. These are shown in the table below:

o	n	bin	root r	q polynomial	OEIS	root of
2	1	11	$\varphi = 1.618\cdots$	$q_1 = 0.618\cdots$		
3	2	101	$1.465571\cdots$	$q_1 = 0.46557123187676\cdots$	A088559	$q^3 + 2q^2 + q - 1$
				$q_{01} = 0.68232780382801\cdots$	A263719	$q^3 + q - 1$
	3	111	$1.839286\cdots$	$q_1 = 0.83928675521416\cdots$		$q^3 - 2q^2 - 2$
4	4	1001	$1.380277\cdots$	$q_1 = r - 1$		
				$q_{01} = 0.52488859865640\cdots$	A072223	$q^4 - 2q^2 - q + 1$
				$q_{001} = 0.72449195900051\cdots$		
	6	1101	$1.7548776\cdots$	$q_1 = r - 1$	A075778	$q^3 + q^2 - 1$
				$q_{11} = 0.32471795724474\cdots$	silver - 1	
				$q_{011} = 0.56984029099805\cdots$		
	7	1111	$1.9275619\cdots$	$q_1 = r - 1$		
				$q_{11} = 0.78793319384471\cdots$		
				$q_{111} = 0.51879006367588\cdots$		

As may be seen, some of these constants are already notable for various reasons. Many are also the real roots of yet other polynomials, of a not entirely obvious form. (Well, the q_1 polynomials will always be obvious expansions in binomial coefficients). The suggestion here is that these are all in turn part of some filigreed partially-ordered set of intertwining polynomials. Exactly how to express that intertwining in any sort of elegant or insightful way is not obvious.

6 Beta Odometer

Examining figure 24 allows some guesswork for the sequences. These are shown in the table below. All such sequences are characterized by a “leader” or “primary”, which

is the largest discontinuity appearing in the figure, followed by its doubling sequence, which always appears to the left of the leader. The leader and its doubling sequence is always bracketed by previous left and right leaders. This, the primary is identified by its bracket: its the largest discontinuity within the bracket. The left-most bracket will be taken as ∞ and the right-most as 0.

Let ℓ be the number of the left bracket, and ρ be the right bracket and f the number of the leader. The numbering of any given polynomial is then $n = f \cdot 2^k$ for $k = 0, 1, 2, \dots$. This is, of course, the very same n as in the previous tables; it is the label of the polynomial $p_n(\beta)$. It is convenient to provide two tables; the first characterizes the sequences to the right of 1, and the second table for those to the left. This helps avoid some confusion.

left ℓ	right ρ	leader f	notes
∞	0	1	main sequence
1	0	3	
$2^m - 1$	0	$2\ell + 1$	right sequence
6	3	13	
$3 \cdot 2^{k+1}$	$3 \cdot 2^k$	$2\ell + 1$	2nd right sub-sequence

The left sequences are in the table below.

left ℓ	right ρ	leader f	notes
∞	0	1	main sequence
2	1	10	
2^{k+1}	2^k	$\ell(2\ell + 1)$	left sub-sequence

The tables are confusing to read, because the left and right brackets are not arbitrary, but must consist of previous leaders or points in their sequences. To provide order for this purpose, continued fraction notation, in the form of $[m_1, m_2, m_3, \dots]$ is convenient. Elements of the main sequence are denoted by $[k]$ which has the numerical value of $n = 2^k = [k]$ for the doubling sequence. Valid left and right brackets on the main sequence are thus $\ell = [k]$ and $\rho = [k-1]$. A valid leader f needs to be bracketed by these two. We need a unique symbol for the bracketing relationship, to avoid confusion with conventional numerical inequalities. Thus, write $\ell \Rightarrow f \Leftarrow \rho$. Numerically, it is also the case that $\ell > f < \rho$, although bracketing requires that numerically, $\ell > \rho$.

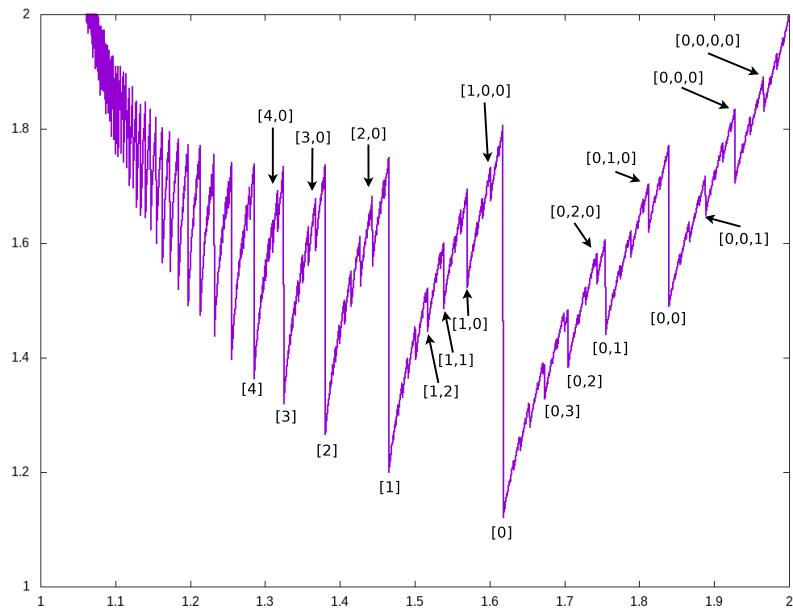

The leader of the left sub-sequence can then be denoted as $[k, 0]$ and the rest of the sub-sequence as $[k, m]$. The bracketing is $[k] \Rightarrow [k, m] \Leftarrow [k-1]$. Apparently, the numerical value is $[k, 0] = 2^k (2^{k+1} + 1) = [k]([k+1] + 1)$ and thus

$$[k, m] = 2^{k+m} (2^{k+1} + 1) = 2^{k+m} (2[k] + 1) = [k+m]([k+1] + 1)$$

Comparing against the figure, one has $[1, 0] = 10$ and $[2, 0] = 36$ and so on. The utility of these labels is shown in figure 27.

The leader of the right sequence is $3 = [0, 0]$ and the rest of that sequence is $6 = [0, 1]$ and generally $3 \cdot 2^m = [0, m]$. The bracketing in play is $[0] \Rightarrow [0, m] \Leftarrow [-1]$ and so the right most point of $\beta = 2$ can be identified with $[-1]$.

Figure 27: Discontinuity Labels

This figure shows the integral $I(\beta) = \sum_{n=0}^{\infty} \beta^{-n} T^n\left(\frac{\beta}{2}\right)$ with $1 < \beta \leq 2$ running along the horizontal axis. Each discontinuity corresponds to the location of a real root of one of the β -Golden polynomials. Prominent discontinuities are labeled with a “continued-fraction”-style labelling.

Consider the subseries lead by $[1, 0] \Rightarrow f \Leftrightarrow [0]$. One has $f = 42 = 2(2[1, 0] + 1) = [1, 0, 0]$. The bracketing in general is then $[1, 0] \Rightarrow [1, 0, p] \Leftrightarrow [0]$ having the numeric value of $n = [1, 0, p] = 2^{p+1}(2[1, 0] + 1) = 2^p \cdot 42$.

Up to three levels, the required bracketing reads as

$$\begin{aligned}[k, m] &\Rightarrow [k, m, p] \Leftrightarrow [k, m - 1] \text{ when } m \geq 1 \\ [k, 0] &\Rightarrow [k, 0, p] \Leftrightarrow [k - 1] \text{ when } k \geq 1 \\ [0, 0] &\Rightarrow [0, 0, p] \Leftrightarrow [0, 0, 0]\end{aligned}$$

As a short-hand, write $[k, -1] = [k - 1]$ when $k \geq 1$ but otherwise $[0, -1] = [0, 0, 0]$. We can deduce that the numbering goes as

$$[k, m, p] = 2^{k+p}(2[k, m] + 1) = 2^{k+p}([k, m + 1] + 1)$$

At four levels, we have $[0, 0, 0, 0] = 2[0, 0, 0] + 1$ and generally $[0, 0, 0, q] = 2^q(2[0, 0, 0] + 1)$. The full expression is

$$[k, m, p, q] = 2^{k+m+q}(2[k, m, p] + 1)$$

That's enough to spot the pattern; it is recursively given by

$$[m_1, m_2, \dots, m_k] = 2^{m_k + m_1 + m_2 + \dots + m_{k-2}}(2[m_1, m_2, \dots, m_{k-1}] + 1) \quad (30)$$

The bracketing relationship is

$$[m_1, m_2, \dots, m_{k-1}] \Rightarrow [m_1, m_2, \dots, m_k] \Leftrightarrow [m_1, m_2, \dots, m_p - 1] \quad (31)$$

where p is the largest integer $1 < p \leq k - 1$ for which $m_p \neq 0$. The bracketing relationship is vitally important for constructing infinite sequences, and proving their convergence. That is, let $\beta = \beta([m_1, m_2, \dots, m_k])$ be the root of the polynomial determined by $[m_1, m_2, \dots, m_k]$. This root can be directly computed as the convergent of a β -Fibonacci sequence, as will be demonstrated in an upcoming section. The relevant point here is that, as numerical values, one has that

$$\beta([m_1, m_2, \dots, m_{k-1}]) < \beta([m_1, m_2, \dots, m_k]) < \beta([m_1, m_2, \dots, m_p - 1])$$

The inequalities are strict. Thus, any given finite-length sequence is bounded above and below by two convergents. This allows infinite-length sequences $[m_1, m_2, \dots]$ to be defined without ambiguity: they are always bounded above and below, by increasingly tight bounds, and so have a unique convergent.

The resulting sequences can be placed into descending order via a recursive algorithm:

```
# Print sequences in descending beta order
# The 'sequence' is the list [m_1, m_2, ... , m_k]
# The 'maxlength' parameter limits recursion to short sequences (max k)
# The 'maxdepth' parameter limits the largest value of each m_j
define iterate (sequence, maxlength, maxdepth)
```

```

# First, iterate to maximum length,
# appending a zero to the end of the sequence.
if (length(sequence) < maxlen)
    iterate (append (sequence, 0), maxlen, maxdepth)

# Output the resulting sequence.
print(sequence)

# Next, increment the tail element of the sequence
# and recurse.
if (tail(sequence) < maxdepth)
    tail(sequence) += 1
    iteratake (sequence, maxlen, maxdepth)

```

The above algorithm will generate polynomials in β -order, that is, in an order such that the one real root of each polynomial is less than the previous one. Printing starts at $\beta = 2$ and descends from there. The starting point is evident, as one has the identity

$$[0, 0, 0, \dots] = [-1]$$

which is associated with $\beta = 2$.

Now we have to prove that the above statements are actually correct. Specifically: that the recursive formula 30 generates only valid polynomials, and that the recursive algorithm generates polynomials in an order such that the real roots appear in proper order. As a side effect, the number of polynomials at each order should be correct: that is, they should be described by the necklace counting function.

Some identities are apparent:

$$\begin{aligned} [0, 0, 0, \dots] &= [-1] \\ [1, 0, 0, \dots] &= [0] = [1, -1] \\ [k, 0, 0, \dots] &= [k-1] = [k, -1] \\ [m_1, m_2, \dots, m_k, 0, 0, \dots] &= [m_1, m_2, \dots, m_k - 1] = [m_1, m_2, \dots, m_k, -1] \end{aligned}$$

These identities are meant to be interpreted as the values of limiting sequences. For example, for the second identity, one has that, for a 1 followed by n zeros, that

$$\begin{aligned} [1, 0, \dots, 0] &\rightarrow \beta^{2n+3} - \beta^{2n+2} - \beta^{2n} - \dots - 1 \\ &= \frac{(\beta^2 - \beta - 1) \beta^{2n+3} + 1}{\beta^2 - 1} \end{aligned}$$

and so in the limit of large n , the root of this polynomial approaches φ .

The encoding can almost be read off directly from the bit sequence. But not quite ... see the table below.

order	n	binary	sequence
2	1	11	[0]
3	2	101	[1]
	3	111	[0,0]
4	4	1001	[2]
	6	1101	[0,1]
	7	1111	[0,0,0]
5	8	10001	[3]
	10	10101	[1,0]
	12	11001	[0,2]
	13	11011	[0,1,0]
	14	11101	[0,0,1]
	15	11111	[0,0,0,0]

Recall that the binary representation for a polynomial is in terms of the binary string of $2n + 1$. Comparing the binary string to the sequence, it seems like the sequence is counting the number of 0's appearing between intervening 1's. Almost. This breaks down at $n = 10$, which “should” have a label of [1,1], instead of [1,0], which “should” describe 5=1011. Except, of course, $n = 5$ is missing, because it is a multiple of $n = 1$. (That is, $n = 5$ corresponds to $\beta^4 - \beta^3 - \beta - 1$ which is a multiple of $\beta^2 - \beta - 1$ and thus cannot appear in the list.) The label that “should” have described 5 instead appears as the label for 10. Alas, this simple way of reading the sequence labels from the list fails.

Lets not give up so easy. The $n = 10$ line is the only line with two non-consecutive 0's in the table. Perhaps the first 0 defines the “new normal”?

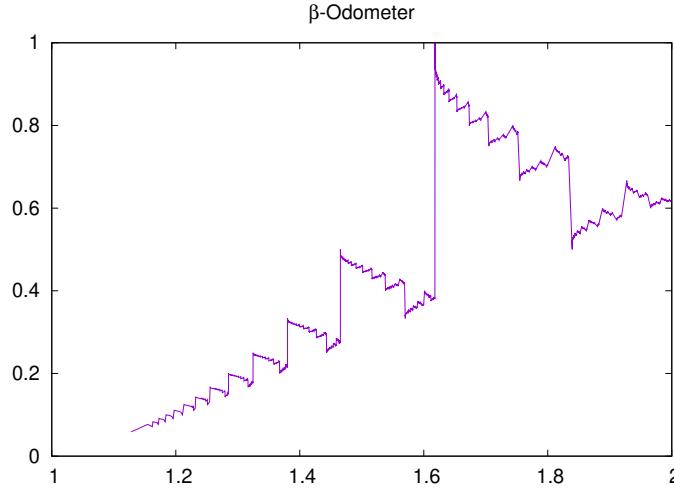

order	n	binary	sequence
5	16	100001	[4]
	20	101001	[1,1]
	24	110001	[0,3]
	25	110011	[0,2,0]
	26	110101	[0,1,1]
	28	111001	[0,0,2]
	29	111011	[0,0,1,0]
	30	111101	[0,0,0,1]
	31	111111	[0,0,0,0,0]

Well, this new proposal seems to ... almost work. We can rationalize away $n = 20$ as following the “new normal”, but then $n = 26$ breaks this rule. Alas. If we persist, I suppose we’ll eventually invent a visual way of reading off eqn 30, but it seems to become too complicated for any easy visual prestidigitation.

6.1 β -Odometer

The continued fraction expansion can be seen to be an odometer that is of characteristic zero. This is unusual, as odometers are conventionally described in characteristic p . A quick review of the concept of an odometer is in order.

Figure 28: Beta odometer

This visualizes the β -odometer in terms of continued fractions. Any given sequence $[m_1, m_2, \dots, m_k]$ has an associated β value; this is graphed on the horizontal axis. It also can be interpreted as a continued fraction, this is shown on the vertical axis. It is clearly self-similar. Some of the vertical joins are drawn not quite vertical; this is due to insufficient convergence during graph generation.

An odometer of characteristic p is defined as the set of all infinite-length integer sequences (a_0, a_1, \dots) with each a_k drawn from the cyclic group $\mathbb{Z}/p\mathbb{Z}$. This set is endowed with a transition function T given by the map

$$T(a_0, a_1, \dots) \mapsto (0, \dots, 0, a_k + 1, a_{k+1}, \dots) \text{ if } (a_0, a_1, \dots) = (p-1, \dots, p-1, a_k, a_{k+1}, \dots)$$

That is, it increments a_0 by one, and if that rolls over, then a carry bit is propagated to the next term, and so on. This is just p -adic addition, treated as a dynamical system. It can also be interpreted as a map of the unit interval, to itself, when the sequence (a_0, a_1, \dots) is interpreted as $x = \sum_n a_n p^{-n-1}$. As a map of the unit interval, it permutes a countable sequence of intervals of decreasing size.

The β -odometer is defined as the bijection that arises by interpreting a sequence $[m_1, m_2, \dots, m_k]$ either as specifying a β value or a continued fraction. The β value is of course, the root of the corresponding polynomial; this root can be computed directly, as a convergent of a β -Fibonacci series, as shown in a later section. The corresponding continued fraction is

$$c = c([m_1, m_2, \dots]) = \frac{1}{m_1 + 1 + \frac{1}{m_2 + 1 + \dots}}$$

where this differs from the conventional definition, being off-by-one, because the m_k can be zero. It is visualized in figure 28.

That the mapping is a bijection is not hard to demonstrate. Certainly, for finite-length sequences, continued fractions are rationals; each such sequence determines a unique rational, and thus the periodic β orbits are mapped to the rationals in this way (thus, the map is an injection). Most orbits of the β -transform are not periodic, however; these map to infinitely long sequences of bits in the bit expansion. The bracketing relation 31 guarantees that an infinitely sequence is bounded above and below by pairs of finite sequences. The bound applies not only to the sequences, but also to the corresponding β values. The bounds are increasingly tight as the sequence lengthens; by standard epsilon-delta arguments, the convergent is unique for infinite-length series. That is, each distinct non-periodic value of β corresponds to a single, unique infinite sequence $[m_1, m_2, \dots]$. It is not hard to see that all possible such sequences occur. Likewise, every irrational number corresponds to a unique infinite-length continued fraction; again, every possible sequence occurs. Thus, the odometer provides a bijection between irrationals and non-periodic orbits. The only difficulty is presented by the rationals: any given rational number has several inequivalent continued fraction expansions, and is thus not strictly invertible. This difficulty is easily swept away by adopting an expansion convention: *e.g.* by taking the shortest possible continued fraction representation for any given rational. In this way, one sees that the odometer is a bijection.

The use of the word “odometer” is perhaps a bit cryptic. The rationale for this can be clarified by looking at how it “rolls over”. The prototypical roll-over occurs at the juncture of $\beta = \varphi = 1.618\dots$. One observes the sequence

$$\begin{aligned} [0, 1] &= \beta = 1.75488\dots \\ [0, 2] &= \beta = 1.70490\dots \\ &\vdots \\ [0, 16] &= \beta = 1.61816\dots \\ [0, N] &= \beta > \varphi \text{ for } N \rightarrow \infty \\ [0] &= [1, -1] = [1, 0, 0, \dots] = \beta = \varphi \\ [1, 0, 0, \dots, 1, \dots] &= \beta < \varphi \end{aligned}$$

That is, the sequence $[0, N]$ for $N \rightarrow \infty$ rolls over to $[1, 0, 0, \dots]$. It is this peculiar behavior that merits the name “odometer”.

Unlike the p -adic case, there is no way to increment the odometer by one unit. The best one can do is to write out the expansion for β , decrement by some arbitrarily small ε and notice that the expansion for $\beta - \varepsilon$ has rolled over at some location. The increment is, formally speaking, an infinitesimal.

This can be compared to how continued fractions roll over. Using our off-by-one notation, write

$$[1, N] = \frac{1}{2 + \frac{1}{N+1}} = 0.5 - \varepsilon$$

which rolls over to

$$[0, 0, 0, \dots, 1, \dots] = \frac{1}{1 + \frac{1}{1 + \frac{1}{\dots}}} = 0.5 + \varepsilon$$

which is, in a sense, backwards: the sequence $[1, N]$ for $N \rightarrow \infty$ does not roll over to $[2, 0, 0, \dots]$ as one might hope or guess or expect, but instead to $[0, 0, 0, \dots]$.

The p -adic odometers are interval maps; they re-arrange countable sequences of subintervals of the unit interval. Here, likewise, the beta odometer rearranges intervals, at least in the sense that rearrangements are disjoint. So, the interval $(\varphi, 2)$ is mapped to $(\frac{1}{2}, 1)$ albeit in a fractal manner, and likewise each subinterval bounded by the descending series of roots to $\beta^n - \beta^{n-1} - 1 = 0$ is mapped to the interval $(\frac{1}{n}, \frac{1}{n-1})$. By self-symmetry, the sub-intervals will re-arrange as well.

6.2 Odometer symmetry and the Vandermonde matrix

A precise expression for the self-symmetry is easy to write in symbolic form. There are two, actually; one is a shift:

$$g : [m_1, m_2, \dots] \mapsto [m_1 + 1, m_2, \dots]$$

and the other is a reflection.

$$r : [m_1, m_2, \dots] \mapsto [1, m_1, m_2, \dots]$$

When the sequences are interpreted as continued fractions, they have a ready expression:

$$c(r([m_1, m_2, \dots])) = c([1, m_1, m_2, \dots]) = 1 - c([m_1, m_2, \dots])$$

that is, $r(x) = 1 - x$; thus a reflection. The shift is likewise a Möbius transformation: $g(x) = x/(x+1)$. Together, these two generate the dyadic monoid. That is, a general expression $\gamma = g^a \circ r \circ g^b \circ \dots$ is still a self-symmetry, where $g^n(x) = x/(nx+1)$. Such elements can be put in one-to-one correspondence with the infinite binary tree, i.e. the dyadic monoid.

An explicit expression for g and r for the odometer is not obvious. Numeric work indicates that $g(x) \approx x(1 - x/\varphi^2)$. This works because the roots almost line up.

Let $f_n(\beta) = \beta^{n+1} - \beta^n - 1$ and let φ_n be the (one and only) real root of $f_n(\varphi_n) = 0$. Finally, let $\alpha_n = \varphi_n - 1$. The remapping requires that $g(\alpha_n) = \alpha_{n+1}$ must hold for $n \geq 0$ as an exact identity. The above approximate g approximately obeys this identity. That is, g acts as a (right-)shift on the root sequence.

Certainly, an analytic series can be obtained; its not clear if this series is adequate for describing the self-symmetry. Let's proceed anyway.

Write

$$g(x) = x + \sum_{n=2}^{\infty} g_n x^n$$

This can be solved subject to the above constraints by inverting

$$\begin{bmatrix} 1 & 1 & 1 & \dots \\ \alpha_1 & \alpha_1^2 & \alpha_1^3 & \dots \\ \alpha_2 & \alpha_2^2 & \alpha_2^3 & \dots \\ \vdots & \vdots & \vdots & \ddots \end{bmatrix} \begin{bmatrix} 1 \\ g_2 \\ g_3 \\ \vdots \end{bmatrix} = \begin{bmatrix} \alpha_1 \\ \alpha_2 \\ \alpha_3 \\ \vdots \end{bmatrix}$$

This matrix is (more or less) a Vandermonde matrix. It can be brought into a more explicit form by writing $g_1 = 1$ and $g_0 = 0$ and $\alpha_0 = 1$. Then one has

$$\begin{bmatrix} 1 & \alpha_0 & \alpha_0^2 & \alpha_0^3 & \dots \\ 1 & \alpha_1 & \alpha_1^2 & \alpha_1^3 & \dots \\ 1 & \alpha_2 & \alpha_2^2 & \alpha_2^3 & \dots \\ \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix} \begin{bmatrix} g_0 \\ g_1 \\ g_2 \\ g_3 \\ \vdots \end{bmatrix} = \begin{bmatrix} \alpha_0 \\ \alpha_1 \\ \alpha_2 \\ \vdots \end{bmatrix}$$

which is explicitly an (infinite-dimensional) Vandermonde matrix. Any given finite Vandermonde matrix has a non-vanishing determinant, and is thus invertable. Explicit expressions for the inverse can be readily found on the internet. As a general rule, Vandermonde matrices are known to be highly ill-conditioned, and difficult to invert numerically.[40]. In principle, we can avoid such difficulties, as we have precise definitions for all quantities involved; thus, simpler notation, such as that provided by Rawashdeh[41] overpowers other concerns. Still, it is far too complicated.

The shift nature of this can be more directly illustrated. Let

$$A = \begin{bmatrix} 1 & \alpha_0 & \alpha_0^2 & \alpha_0^3 & \dots \\ 1 & \alpha_1 & \alpha_1^2 & \alpha_1^3 & \dots \\ 1 & \alpha_2 & \alpha_2^2 & \alpha_2^3 & \dots \\ \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix}$$

and

$$T = \begin{bmatrix} 0 & 1 & 0 & 0 & \dots \\ 0 & 0 & 1 & 0 & \dots \\ 0 & 0 & 0 & 1 & \dots \\ \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix}$$

and

$$\alpha = \begin{bmatrix} \alpha_0 \\ \alpha_1 \\ \alpha_2 \\ \vdots \end{bmatrix}$$

Then the above eqn takes the form

$$Ag = T\alpha = TA \begin{bmatrix} 0 \\ 1 \\ 0 \\ \vdots \end{bmatrix}$$

Presuming that A is invertable, then

$$g = A^{-1}TA \begin{bmatrix} 0 \\ 1 \\ 0 \\ \vdots \end{bmatrix}$$

So the desired solution picks out one column from a shift that uses a Vandermonde matrix as the similarity transform.

The rows of A are the iterates of the monomials in a quotient ring. So, first of all, the polynomials $f_n(\beta)$ are irreducible (over \mathbb{Q} ; they have one and only one real root; that root is not a rational number). The quotient ring $\mathbb{Q}[\beta]/f_n$ is thus a field. It's also a vector space, spanned by the monomials $1, \beta, \beta^2, \dots, \beta^n$ as basis vectors, where modulo f_n means that $\beta^{n+1} = \beta^n + 1$. Of course, the root φ_n is an algebraic element of $\mathbb{Q}[\beta]/f_n$ and so L_n is a simple extension of \mathbb{Q} generated by φ_n . The “first ring isomorphism theorem” states that $\mathbb{Q}[\beta]/f_n$ and L_n are isomorphic.

(Note, BTW, that we've broken our convention for n used in the resto of the paper. Everywhere where we have n in this section, it should actually be 2^n to be consistent with earlier notation.)

What is the orbit of φ_n^m for $m \in \mathbb{N}$? Numerically, since $\varphi_n > 1$, taking its powers will clearly blow up. The corresponding β -Fibonacci sequence is $F_{m+1}^{(n)} = F_m^{(n)} + F_{m-n}^{(n)}$ and so one can immediately write $\varphi_n^m = F_m^{(n)}\varphi_n^n + F_{m-1}^{(n)}\varphi_n^{n-1} + \dots + F_{m-n}^{(n)}\varphi_n^0$ as the orbit of φ_n^m in L_n .

In the present case, we have $\alpha_1 = \varphi_1 - 1 = \varphi - 1$ and so $\alpha_1^2 = 1 - \alpha_1 = 2 - \varphi$, and onward: $\alpha_1^3 = 2\alpha_1 - 1$ and $\alpha_1^4 = 2 - 3\alpha_1$ and $\alpha_1^5 = 5\alpha_1 - 3$ and $\alpha_1^6 = 5 - 8\alpha_1$ and so clearly the Fibonacci sequence is showing up. For the next row, we have that $\varphi_2^3 - \varphi_2^2 - 1 = 0$, and so the second row has

$$\begin{aligned}\alpha_2 &= \varphi_2 - 1 \\ \alpha_2^2 &= \varphi_2^2 - 2\varphi_2 + 1 \\ \alpha_2^3 &= -2\varphi_2^2 + 3\varphi_2 \\ \alpha_2^4 &= 3\varphi_2^2 - 3\varphi_2 - 2 \\ \alpha_2^5 &= -3\varphi_2^2 + \varphi_2 + 5 \\ \alpha_2^6 &= \varphi_2^2 + 4\varphi_2 - 8 \\ \alpha_2^7 &= 4\varphi_2^2 - 12\varphi_2 + 9 \\ \alpha_2^8 &= -12\varphi_2^2 + 21\varphi_2 - 5 \\ \alpha_2^9 &= 21\varphi_2^2 - 26\varphi_2 - 7 \\ \alpha_2^{10} &= -26\varphi_2^2 + 19\varphi_2 + 28 \\ \alpha_2^{11} &= 19\varphi_2^2 + 9\varphi_2 - 54 \\ \alpha_2^{12} &= 9\varphi_2^2 - 63\varphi_2 + 73\end{aligned}$$

I am not enlightened by staring at that. Brute force does not appear to work on this.

It's still an interesting problem: each row of the Vandermonde matrix is associated with the polynomial $\beta^{n+2} - \beta^{n+1} - 1 = 0$ and so each row will be some chaotic, iterated polynomial – that is, the β -Fibonacci sequence that delivers φ_n , except that since $\alpha_n = \varphi_n - 1$, each row is multiplied by the Pascal matrix (the matrix of binomial coefficients).

That is,

$$\begin{bmatrix} 1 & \varphi_0 & \varphi_0^2 & \varphi_0^3 & \cdots \\ 1 & \varphi_1 & \varphi_1^2 & \varphi_1^3 & \cdots \\ 1 & \varphi_2 & \varphi_2^2 & \varphi_2^3 & \cdots \\ \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix} \begin{bmatrix} 1 & -1 & 1 & -1 & \cdots \\ 0 & 1 & -2 & 3 & \cdots \\ 0 & 0 & 1 & -3 & \cdots \\ 0 & 0 & 0 & 1 & \cdots \\ \vdots & & \vdots & \ddots & \end{bmatrix} \begin{bmatrix} g_0 \\ g_1 \\ g_2 \\ g_3 \\ \vdots \end{bmatrix} = \begin{bmatrix} \alpha_0 \\ \alpha_1 \\ \alpha_2 \\ \vdots \end{bmatrix}$$

However, this is ill-conditioned. For the matrix A , we had $1 > \alpha_n^m$ for all m, n and even $\alpha_n > \alpha_{n+m}$ for all m, n so A seems well-behaved I guess that means A^{-1} is poorly behaved. Here, its worse; one has $1 < \varphi_n^m$ for all m, n so everything blows up.

What else can we do? Well, there's this: write $f_n(\beta) = \beta^{n+1} - \beta^n - 1$ and note that these are easily generated recursively: $f_{n+1}(\beta) = \beta f_n(\beta) + \beta - 1$. The ordinary generating function is easy to find:

$$\sum_{n=0}^{\infty} y^n f_n(\beta) = \frac{y + \beta - 2}{(1-y)(1-y\beta)}$$

7 Galois extensions

The β -golden polynomials defined in the last section form a curious class. One can now embark down a path of arithmetic. For each such polynomial (or analytic series, as the case may be) and given some field K (for example, say, the rationals \mathbb{Q}), one can construct the Galois extension $K(\beta) : K$.

For the case of β periodic, there is just one real root φ_n , and it is not rational. This root is an algebraic element of the polynomial ring $\mathbb{Q}[\beta]$ (obviously), and so it generates the (simple) field extension $\mathbb{Q}(\varphi_n)$. The order of the polynomial $p_n(\beta)$ is $\lfloor \log n \rfloor + 1$ and so this is obviously the transcendence degree of the field extension. The elements φ_n^m for $0 \leq m \leq \lfloor \log n \rfloor$ provide the basis.

For the case of β aperiodic, the vector space is clearly infinite-dimensional.

A few questions:

- What is the automorphism group?
- What is the field of fractions?

8 Islands of Stability as Arnold Tongues

The trouble-spots, the eventual fixed-points of the map, can be placed in one-to-one accordance with the “islands of stability” seen in the iterated logistic map. They are, in essence, locations where periodic orbits “could be pasted”, or where they “naturally would appear”, if the map supported periodic attractors. That is, the beta shift only supports a single attractor, of period-one at $x = 0$; there is no “room” for anything more. This is analogous, in a way, to the phase locked loop, at zero coupling constant. At finite coupling strength, these “trouble spots” expand out as Arnold tongues, to have

a finite size, visible on the Feigenbaum diagram for the logistic map as regions where period-doubling is occurring.

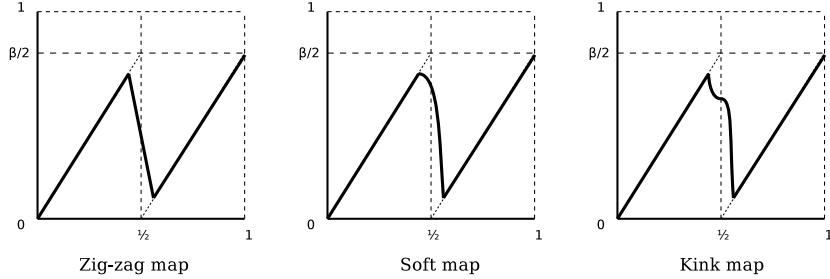

The idea here can be illustrated explicitly. Basically, take the natural sawtooth shape of the map, widen the middle, and insert a slanting downward line, to create a zig-zag. That is, connect the two endpoints in the middle of the beta shift, “widening” it so that it has a finite, not infinite slope, thereby converting the iterated function from a discontinuous to a continuous one. This can be constructed directly: given some “small”, real $\varepsilon > 0$, define the piecewise-linear ε -generalization of the map 4 as

$$T_{\beta,\varepsilon}(x) = \begin{cases} \beta x & \text{for } 0 \leq x < \frac{1}{2} - \varepsilon \\ \frac{\beta}{4} - \beta \left(\frac{1}{4} - \varepsilon\right) w & \text{for } \frac{1}{2} - \varepsilon \leq x < \frac{1}{2} + \varepsilon \\ \beta \left(x - \frac{1}{2}\right) & \text{for } \frac{1}{2} + \varepsilon \leq x \leq 1 \end{cases} \quad (32)$$

where w is just a handy notation for a downward sloping line:

$$w = \frac{2x - 1}{2\varepsilon}$$

Observe that $w = 1$ when $x = \frac{1}{2} - \varepsilon$ and that $w = -1$ when $x = \frac{1}{2} + \varepsilon$ so that w just smoothly interpolates between +1 and -1 over the middle interval. The additional factors of $\frac{\beta}{4} - \beta \left(\frac{1}{4} - \varepsilon\right) w$ just serves to insert the downward slope smack into the middle, so that the endpoints join up. The results is the zig-zag map, illustrated in the figure below

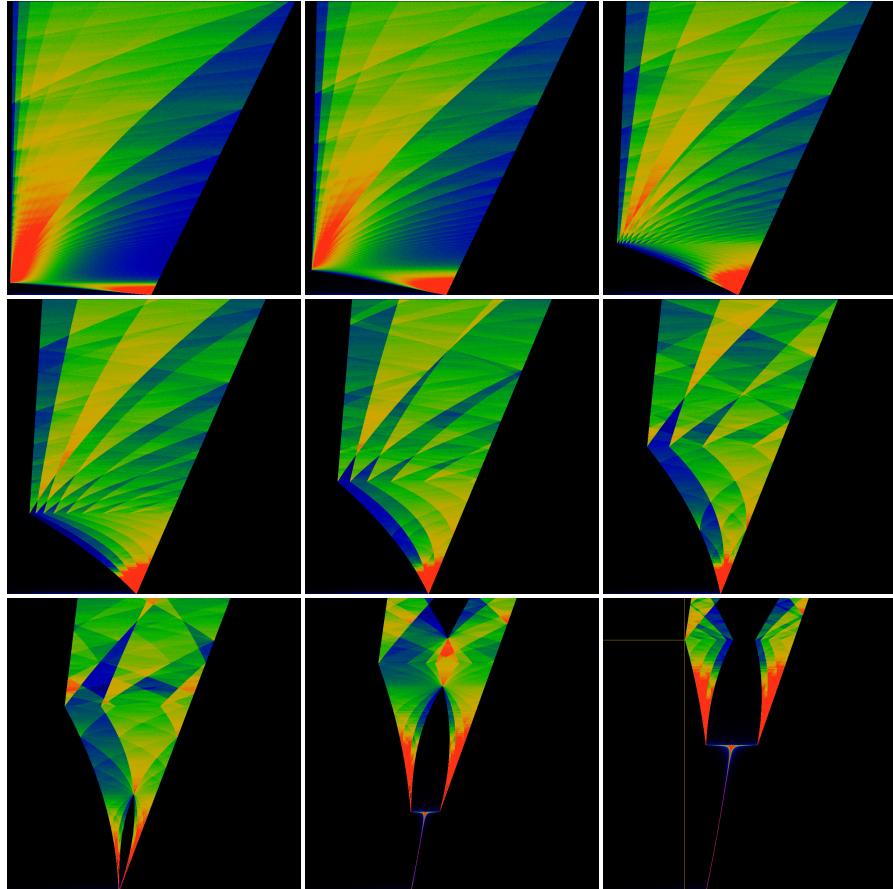

In the limit of $\varepsilon \rightarrow 0$, one regains the earlier beta shift: $\lim_{\varepsilon \rightarrow 0} T_{\beta,\varepsilon} = T_\beta$, as the slope of the middle bit becomes infinite. The middle segment is a straight line; it introduces another folding segment into the map. This segment introduces a critical point only when ε is sufficiently large, and β is sufficiently small, so that its slope is less than 45 degrees (is greater than -1). When this occurs, a fixed point appears at $x = 1/2$. A sequence of images for finite ε are shown in figure 29.

The appearance of islands of stability in the Feigenbaum attractor is due to the presence of a fixed point at any parameter value. In order to “surgically add” islands of stability to the beta transform, the middle segment interpolation must also have a critical point at “any” value of ε . To achieve this, consider the curve

$$D_{\beta,\varepsilon}(x) = \begin{cases} \beta x & \text{for } 0 \leq x < \frac{1}{2} - \varepsilon \\ \frac{\beta}{4} - \beta \left(\frac{1}{4} - \varepsilon\right) g(w) & \text{for } \frac{1}{2} - \varepsilon \leq x < \frac{1}{2} + \varepsilon \\ \beta \left(x - \frac{1}{2}\right) & \text{for } \frac{1}{2} + \varepsilon \leq x \leq 1 \end{cases} \quad (33)$$

Figure 29: Z-shaped Map

This illustrates a sequence of iterated maps, obtained from eqn 32. Shown are $\varepsilon = 0.01, 0.02, 0.04$ in the first row, $0.06, 0.08, 0.10$ in the second row and $0.12, 0.14, 0.15$ in the third row. The image for $\varepsilon = 0$ is, of course, figure 2. The parameter β runs from 1 at the bottom to 2 at the top. Thus, a horizontal slice through the image depicts the invariant measure of the iterated map, black for where the measure is zero, and red where the measure is largest. The sharp corner at the lower-left is located $\beta = (1 + 2\varepsilon) / (1 - 2\varepsilon)$ and $x = \varepsilon(1 + 2\varepsilon) / (1 - 2\varepsilon)$. A yellow horizontal and vertical line in the last image indicate the location of this corner.

where the straight line has been replaced by a soft shoulder

$$g(w) = 1 - 2 \cos \frac{\pi}{4} (1 + w)$$

and w is the same as before. This is scaled so that its a drop-in replacement for the straight line: $g\left(\frac{1}{2} - \varepsilon\right) = 1$ and $g\left(\frac{1}{2} + \varepsilon\right) = -1$. A cosine was used to create this soft shoulder, but a parabola would have done just as well. It is illustrated above, with the label “soft map”.

This map also interpolates between the left and right arms of the beta transform, forming a single continues curve. The curve is smooth and rounded near $\frac{1}{2} - \varepsilon \lesssim x$, having a slope of zero as x approaches $\frac{1}{2} - \varepsilon$ from above. This introduces a critical point near $\frac{1}{2} - \varepsilon$. Notice that there is a hard corner at $\frac{1}{2} + \varepsilon$. The interpolation is NOT an S-curve! A sequence of images for finite ε are shown in figure 30.

Two more variant maps can be considered. Both replace the center piece with symmetrical sinuous S-shaped curves, but in different ways. Consider

$$S_{\beta,\varepsilon,\sigma}(x) = \begin{cases} \beta x & \text{for } 0 \leq x < \frac{1}{2} - \varepsilon \\ \frac{\beta}{4} - \sigma \beta \left(\frac{1}{4} - \varepsilon\right) \sin \frac{\pi}{2} w & \text{for } \frac{1}{2} - \varepsilon \leq x < \frac{1}{2} + \varepsilon \\ \beta \left(x - \frac{1}{2}\right) & \text{for } \frac{1}{2} + \varepsilon \leq x \leq 1 \end{cases} \quad (34)$$

and

$$H_{\beta,\varepsilon,p,\sigma}(x) = \begin{cases} \beta x & \text{for } 0 \leq x < \frac{1}{2} - \varepsilon \\ \frac{\beta}{4} - \sigma \beta \left(\frac{1}{4} - \varepsilon\right) \operatorname{sgn}(x - \frac{1}{2}) |w|^p & \text{for } \frac{1}{2} - \varepsilon \leq x < \frac{1}{2} + \varepsilon \\ \beta \left(x - \frac{1}{2}\right) & \text{for } \frac{1}{2} + \varepsilon \leq x \leq 1 \end{cases} \quad (35)$$

The $S_{\beta,\varepsilon}(x)$ replaces the central segment with a softly-rounded segment, containing two critical points: near $\frac{1}{2} - \varepsilon$ and near $\frac{1}{2} + \varepsilon$, where the curve flattens out to a zero slope. When $\sigma = +1$, the map as a whole is continuous. When $\sigma = -1$, the map consists of three discontinuous pieces. Different values are explored in figure 31.

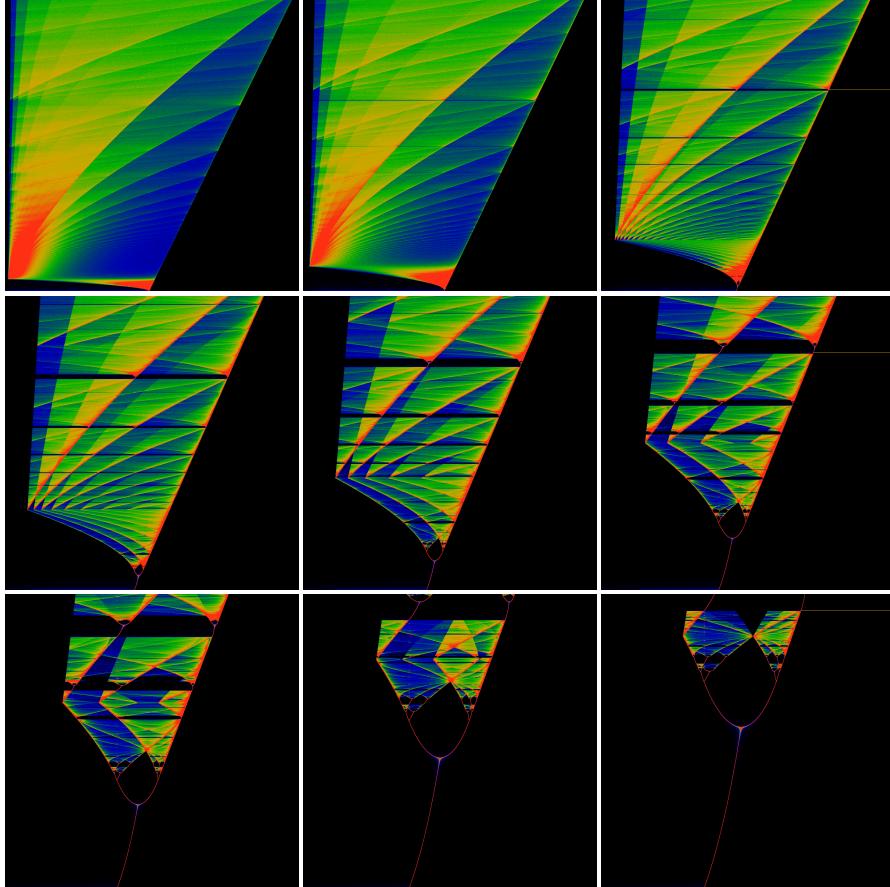

The $H_{\beta,\varepsilon,p,\sigma}(x)$ replaces the central segment with a segment that has a kink in the middle, when $p > 1$. Note that $H_{\beta,\varepsilon,1,1}(x) = T_{\beta,\varepsilon}(x)$. Here, $\operatorname{sgn} x$ is the sign of x . The general shape of $H_{\beta,\varepsilon,p,\sigma}(x)$ is shown above, labeled as the “kink map”. The location of the kink in H is always centered; an off-center kink, as depicted in the figure, is explored below. The bifurcation diagrams for H are illustrated in figure 32.

To summarize: the “trouble spots” aren’t “just some periodic orbits” at certain values of β : they are more “fundamental” than that: they indicate the regions where (“phase-locked”) periodic orbits can be made to appear. And conversely: bifurcations can only appear here, and not elsewhere! The last sequence of images, shown in figure 32 indicate that the islands of stability need NOT consist of the period-doubling sequences seen in the Feigenbaum map. This is made explicit in figure 33, which shows a zoom by a factor of thirty.

Another interesting visualization is a Poincaré recurrence plot. The islands of stability should manifest as Arnold tongues[42]. These are shown in figures 34 and 35.

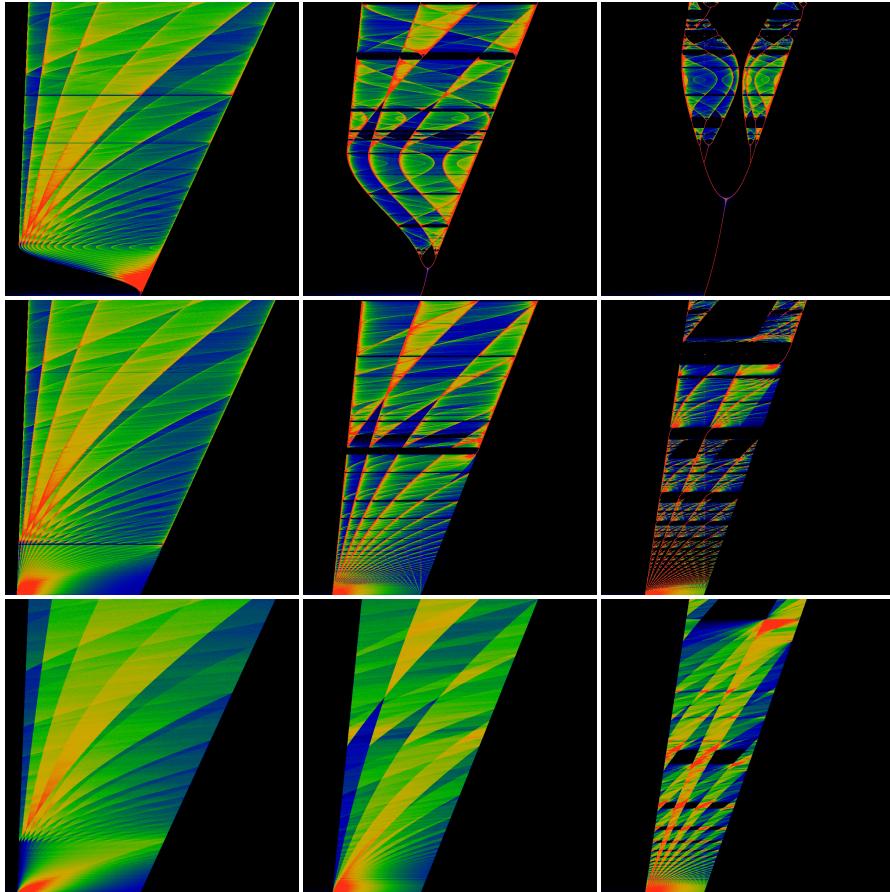

To intuitively understand the location of the islands (the location of the Arnold tongues), its easiest to examine a map with a kink in it, whose location is adjustable.

Figure 30: Critical-Z map

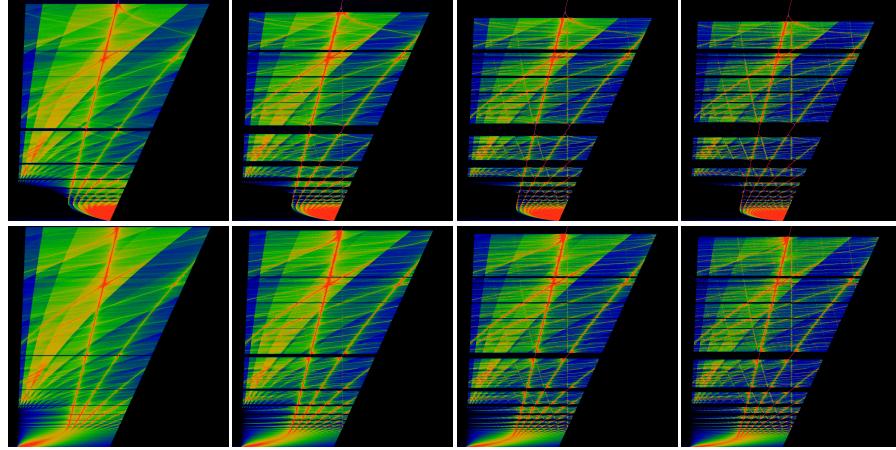

This illustrates a sequence of iterated maps, obtained from eqn 33. The sequence of depicted ε values are the same as in figure 29. The top row shows $\varepsilon = 0.01, 0.02, 0.04$, with $0.06, 0.08, 0.10$ in the second row and $0.12, 0.14, 0.15$ in the bottom row. The image for $\varepsilon = 0$ is, of course, figure 2. The parameter β runs from 1 at the bottom to 2 at the top. Working from bottom to top, one can see islands of stability forming in the $\varepsilon = 0.02$ and 0.04 images. The largest island, one third from the top, corresponds to $\beta = \varphi = 1.618\cdots$ the golden ratio. Moving downwards, the other prominent islands correspond to the “trouble spots” 101, 1001 and 1001, which are the Narayana’s Cows number, an un-named number, and the Silver Ratio, at $\beta = 1.4655\cdots$ and so on. Moving upwards, one can see a faint island at the tribonacci number. Due to the general asymmetry of the map, these islands quickly shift away from these limiting values. For example, the primary island appears to start near $\beta = \delta + (2 - \delta)(\varphi - 1)$, where $\delta = (1 + 2\varepsilon) / (1 - 2\varepsilon)$. This location is indicated by a horizontal yellow line in the images in the right column. The other islands shift away in a more complicated fashion.

Figure 31: Interpolating Sine Map

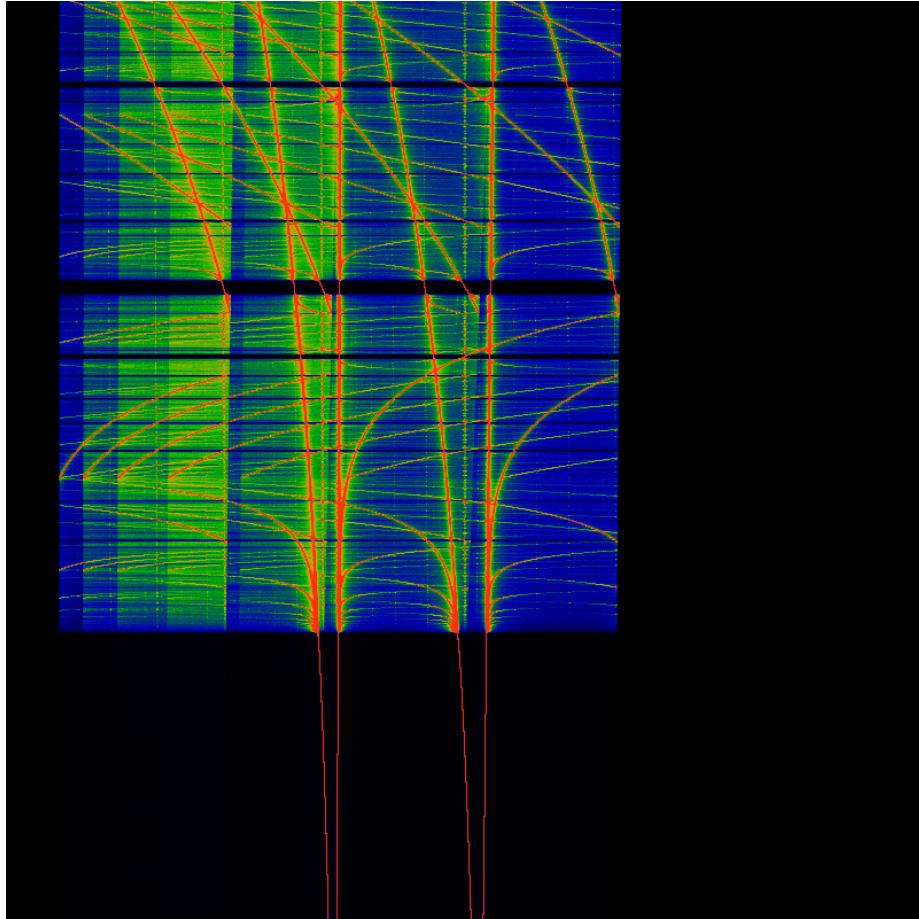

This illustrates a sequence of iterated maps, obtained from eqn 34. The sequence in the upper row shows $\epsilon = 0.04, 0.10$ and 0.15 ; with $\sigma = +1$. The upper row is much like the sequence shown in figure 30, except that its made sinuous, thanks to symmetrical S-shape. The middle row shows the same ϵ values, but for $\sigma = -1$. The bottom row shows eqn 35 with $p = 1$ and $\sigma = -1$; thus, because $p = 1$ gives a straight-line segment in the middle, this bottom row is directly comparable to the zig-zap map. It should make clear that the islands appear in the middle row due to critical points in the S-curve, and not due to the tripartite map. The lower right diagram exhibits islands, but only because the middle segment has a slope of less than 45 degrees, resulting in a critical point at the middle of the map. As usual, the parameter β runs from 1 at the bottom to 2 at the top.

Figure 32: Interpolating Kink Map

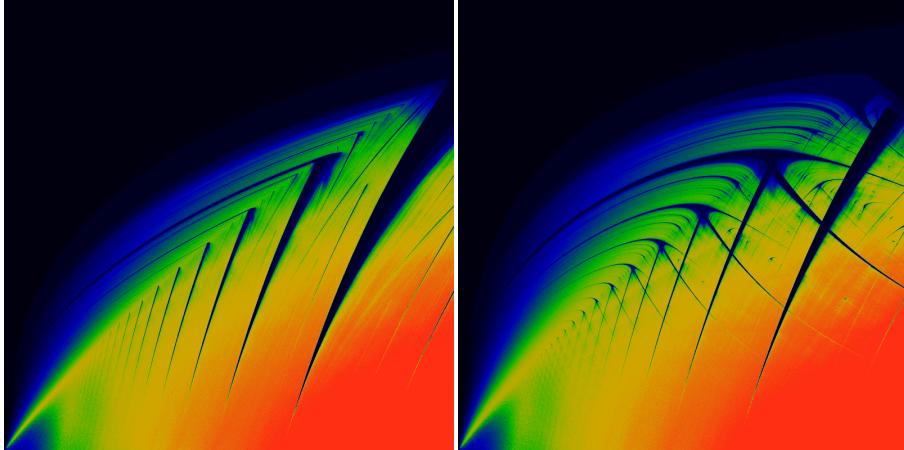

This illustrates a sequence of iterated maps, obtained from eqn 35. All eight images are held at $\varepsilon = 0.04$. The top row has $\sigma = +1$ (and thus the map is continuous) while the bottom row has $\sigma = -1$ (and thus the map has three disconnected branches). Left to right depicts the values $p = 2, 3, 4, 5$. As usual, the parameter β runs from 1 at the bottom to 2 at the top. In all cases, islands appear, and numerous common features are evident. Perhaps most interesting is that the islands do NOT contain period-doubling sequences. The primary sequence of islands, starting from the central largest, proceeding downwards, are located the inverse powers of two, *viz* at $\beta = \sqrt[k]{2}$. Why are the islands located at inverse powers of two, instead or, for example, the golden means? The short answer: it depends on the location of the kink in the map, as explored in the main text.

Figure 33: No Period Doubling

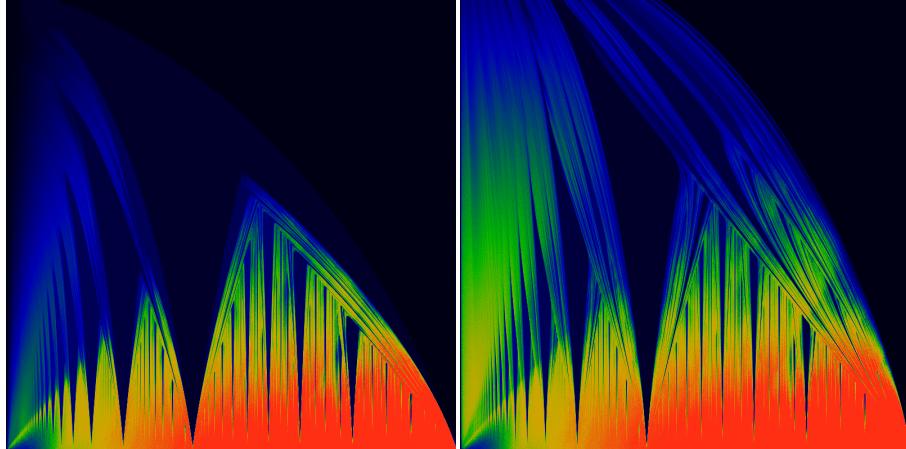

This figure is a zoom, confirming a lack of period doubling in the map $H_{\beta,\epsilon,p,\sigma}(x)$ of eqn 35. The explored region is $0 \leq x \leq 1$, viz no zoom in the horizontal direction. Vertically, the image is centered on $\beta = 1.45$, having a total height of $\Delta\beta = 0.015625$. This uses the quintic kink, so $p = 5$ and $\sigma = +1$, making the continuous variant. The value of $\epsilon = 0.04$ makes this directly comparable to other images.

Figure 34: Poincaré recurrence

The above visualize the Poincaré recurrence times for the map $D_{\beta,\varepsilon}(x)$ of eqn 33 on the left, and the map $S_{\beta,\varepsilon,1}(x)$ of eqn 34 on the right. In both cases, the parameter β runs from 1 to 2, left to right. The parameter ε runs from 0 to 0.2, bottom to top. The Poincaré recurrence time is obtained by iterating on the maps, and then counting how many iterations it takes to get near an earlier point. The color coding is such that yellow/red indicates large recurrence times; green is intermediate time, blue a short time, and black corresponds to n less than 3 or 4 or so. The vertical black spikes are the Arnold tongues; they correspond to parameter regions which lie in an island of stability. That is, the recurrence time is low, precisely because the point x is bouncing between a discrete set of values. The yellow/red regions correspond to chaos, where the iterate x is bouncing between all possible values. The largest right-most spike is located at $\beta = \varphi = 1.618\cdots$, with the sequence of spikes to the left located at the other primary golden means (*viz.*, $1.3803\cdots$ and the silver mean $1.3247\cdots$ and so on). As noted earlier, the general curve of that spike appears to follow $\beta = \delta + (2 - \delta)(\varphi - 1)$, where $\delta = (1 + 2\varepsilon)/(1 - 2\varepsilon)$. The dramatic swallow-tail shapes in the right-hand image are identical to those that appear in the classic iterated circle map.[42]

Figure 35: Arnold Tongues

The above visualize the Poincaré recurrence times for the map $H_{\beta,\epsilon,p,\sigma}(x)$ of eqn 35. The parameter β runs from 1 to 2, left to right. The parameter ϵ runs from 0 to 0.2, bottom to top. The power p is held fixed at $p = 5$. The left image shows $\sigma = -1$; the right shows $\sigma = +1$. The Poincaré recurrence time is obtained by iterating on $H_{\beta,\epsilon,p,\sigma}(x)$ and counting how many iterations it takes until $|x - H_{\beta,\epsilon,p,\sigma}^n(x)| < 0.009$. The shapes depicted are not sensitive to the recurrence delta 0.009; this value is chosen primarily to make the colors prettier. The color coding is such that yellow/red indicates large recurrence times n ; green is intermediate time, blue a short time, and black corresponds to n less than 3 or 4 or so. The vertical blue spikes are the Arnold tongues; they correspond to parameter regions which lie in an island of stability. That is, the recurrence time is low, precisely because the point x is bouncing between a discrete set of values. The yellow/red regions correspond to chaos, where the iterate x is bouncing between all possible values. The central spike is located at $\beta = \sqrt{2}$ with the sequence of spikes to the left located at $\sqrt[k]{2}$ for increasing k . In that sense, the large black region dominating the right side of the figures corresponds to $\beta = 2$. These correspond to the black bands in figure 32.

$$H_{\beta,\varepsilon,\alpha,\sigma}(x) = \begin{cases} \beta x & \text{for } 0 \leq x < \frac{1}{2} - \varepsilon \\ \frac{\beta}{4} - \sigma\beta \left(\frac{1}{4} - \varepsilon\right) h_{\alpha,p} & \text{for } \frac{1}{2} - \varepsilon \leq x < \frac{1}{2} + \varepsilon \\ \beta \left(x - \frac{1}{2}\right) & \text{for } \frac{1}{2} + \varepsilon \leq x \leq 1 \end{cases}$$

with

$$h_{\alpha,p}(x) = \begin{cases} \alpha + (1-\alpha)|w|^p & \text{for } x < \frac{1}{2} \\ \alpha - (1+\alpha)|w|^p & \text{for } \frac{1}{2} \leq x \end{cases}$$

As before, $h_{\alpha,p}(x)$ is designed to interpolate appropriately, so that $h_{\alpha,p}(\frac{1}{2} - \varepsilon) = 1$ and $h_{\alpha,p}(\frac{1}{2} + \varepsilon) = -1$. The location of the kink is now adjustable: $h_{\alpha,p}(\frac{1}{2}) = \alpha$. Iterating on this map results in figures that are generically similar to those of figure 32, except that this time, the location of the islands is controllable by the parameter α . Roughly, to first order, the primary series of islands are located at $\sqrt[k]{2/(1-\alpha)}$; as before, these islands do not allow period-doubling to take place.

To get islands with period doubling, one needs to re-create the “soft shoulder” of eqn 33, but at a variable location.

Thus, the above presents a general surgical technique for controlling both the general form of the chaotic regions, the location of the islands of stability, and what appears within the islands.

Conjectures are fun! The above arguments should be sufficient to fully demonstrate that the circle map, which is well-known to exhibit phase locking regions called Arnold tongues, is topologically conjugate to the fattened beta shift $T_{\beta,\varepsilon}$. Or something like that. In a certain sense, this can be argued to be a “complete” solution, via topological conjugacy, of the tent map, the logistic map and the circle map. This is a worthwhile exercise to actually perform, i.e. to give explicit expressions mapping the various regions, as appropriate.

Essentially, the claim is straight-forward: topologically, all chaotic parts of a map correspond to folding (as per Milnor, 1980’s on kneading maps), into which one may surgically insert regions that have cycles of finite length. The surgical insertion can occur only at the discontinuities of the kneading map. It almost sounds trivial, expressed this way; but the algebraic articulation of the idea would be worthwhile.

9 Miscellaneous unfinished ideas

An ad-hoc collection of half-finished thoughts.

9.1 Multiplicative Shifts

A multiplicative shift is a shift assembled as an product of functions. The most famous of these is the generating function for integer partitions

$$P(z) = \prod_{n=1}^{\infty} \frac{1}{(1-z^n)}$$

Similarly products occur for the necklace counting functions, most famously the cyclotomic identity

$$\frac{1}{1-\beta z} = \prod_{j=1}^{\infty} \left(\frac{1}{1-z^j} \right)^{M(\beta,j)}$$

where $M(\beta, j)$ the necklace polynomial.

A far more obscure product expresses the Minkowski measure[28], given as

$$?'(x) = \prod_{n=0}^{\infty} \frac{A' \circ A^n(x)}{2}$$

with

$$A(x) = \begin{cases} \frac{x}{1-x} & \text{for } 0 \leq x < \frac{1}{2} \\ \frac{2x-1}{x} & \text{for } \frac{1}{2} \leq x \leq 1 \end{cases}$$

with A' being the derivative of A and A^n being the n 'th iterate. The Minkowski measure integrates to the Minkowski Question Mark function $?(y) = \int_0^y ?'(x) dx$; it is the prototypical “multi-fractal measure” (although there really is nothing “multi-” about it; the “multi-” prefix stems from a misunderstanding of its multiplicative invariance). The product structure indicates that the Minkowski measure is a Gibbs measure, viz arising from an invariant Hamiltonian on a one-dimensional lattice.

The figure 23 suggests that a similar product can be constructed from the midpoint sequence, namely

$$\prod_{p=0}^{\infty} \frac{4m_p(\beta)}{\beta}$$

for the midpoints $m_p(\beta) = T_{\beta}^p(m_0)$.

9.2 Midpoints, revisited

The midpoints are defined above as $m_0 = \beta/2$, so that $m_p = T_{\beta}(m_{p-1}) = T_{\beta}^p(m_0)$ with $T_{\beta}(y)$ the beta shift map of eqn 4. Almost all literature uses the beta transform $t_{\beta}(x)$ of eqn 8 instead. The midpoint sequence and the iterate $t_{\beta}^p(1)$ are closely related:

$$2m_p \mod 1 = t_{\beta}^{p+1}(1)$$

Although related, they are not the same. The difference is a sequence of bits:

$$c_p = 2m_p - t_{\beta}^{p+1}(1)$$

Note that $c_p \in \{0, 1\}$ always. Note that

$$\beta = \sum_{p=0}^{\infty} \frac{c_p}{\beta^p}$$

which is not entirely obvious!

9.3 Rauzy Fractals

Given a polynomial, one has an associated finite matrix, in Hessenberg form, that, iterated upon, generates a sequence. The projection of that sequence to a non-expanding orthogonal plane is a Rauzy fractal. What are the corresponding Rauzy fractals for this situation?

How about the general iterated sequence (e.g. the sequence of midpoints)? Is this space-filling, or not?

9.4 Fourier spectrum

What is the fourier spectrum of the eigenfunctions?

10 Bergman (Hessenberg) Polynomials

Given a matrix operator in Hessenberg form, it can be interpreted as a right-shift on the space of polynomials. Such polynomials form an orthogonal basis for a certain kind of Hilbert space, called the Bergman space. They are studied in applied mathematics, as they are orthogonal over some measure on the complex plane. The Hessenberg operator is a generalization of the better-known case of the Jacobi operator, which has its own extensive theory, including spectra and scattering, and is important for several exactly solvable non-linear models in physics, including the Toda lattice[43]. The Hessenberg operator presumably has an equally rich theory, but it does not appear to be currently known; the breadth and scope of existing publications is limited.

The general framework for the Hessenberg polynomials is sketched below, including a fast and informal definition of Bergman space (the space on which the polynomials are orthogonal). The Hessenberg matrix is explicitly solvable on the left, and can be explicitly brought into a form that exhibits the right-shift operator. In the general theory, the change of basis from the shift operator to the Hessenberg matrix is known to be the Cholesky decomposition of a moment matrix, and specifically, the moments of the measure on which the polynomials are orthogonal.

There are two Hessenberg operators in this text: the operator \mathcal{L}_β in the wavelet basis, and the operator \mathcal{H}_β generated from the midpoint orbits. The second is already obviously a shift, and so everything below follows “trivially” from it. The first form is numerically and analytically difficult. Needless to say, the section below treats the first rather than the second. XXX TODO this should be fixed, as \mathcal{H}_β is both simpler and more enlightening overall. Later ...

Working backwards from the beta shift, the first asymptotic term in the measure can be extracted. For $\beta > \varphi$, it appears to be a Dirac delta (point mass) located at $z = 1$ on the complex plane, with a blancmange-like fractal curve giving the weight. For $\beta < \varphi$, it appears to be the derivative of the Dirac delta, with a different blancmange-like fractal curve giving the weight.

10.1 Bergman Space

Given a matrix operator in Hessenberg form, it can be interpreted as a right-shift on the space of polynomials. That is, given an unreduced Hessenberg matrix with matrix entries A_{ij} , one can write a recurrence relation that defines a sequence of polynomials as

$$zp_n(z) = \sum_{k=0}^{n+1} A_{kn} p_k(z) \quad (36)$$

with $p_0(z) = 1$. This relation is easily solvable in closed form, as the recurrence relation terminates in a finite number of steps.

One important property of these polynomials is that the zeros of $p_n(z)$ correspond to the eigenvalues of the $n \times n$ principle submatrix of A . Numeric exploration of these polynomials confirms the previous results on eigenvalues obtained from direct diagonalization: the zeros of the $p_n(z)$ seems to lie mostly near the circle of radius $1/\beta$, distributed uniformly over all angles.

If all of the sub-diagonal entries obey $A_{n+1,n} > 0$, then the polynomials form an orthonormal basis for Bergman space. That is, there exists a domain in the complex plane on which the polynomials provide a basis for a Hilbert space of holomorphic functions on that domain[44, 45, 46]. That is, one has the orthogonality relation

$$\delta_{mn} = \int_D p_m(\bar{z}) p_n(z) d\mu(z)$$

for some domain $D \subset \mathbb{C}$ of the complex plane, and some (Borel) measure $d\mu$ on that domain.

The matrix A can be interpreted as an operator with a continuous spectrum. To do this, fix a certain, specific value of $z = c$ a constant, and then notice that $\vec{p} = (p_n(z))_{n=0}^{\infty}$ is a vector having the property that $A^T \vec{p} = z \vec{p}$. That is, \vec{p} is a left-eigenvector of A ; equivalently, a right-eigenvector of its transpose A^T . Clearly, the spectrum is continuous on the domain D .

The matrix operator A can also be interpreted as a right-shift on Bergman space. To do this, define

$$\mathcal{A}(w, z) = \sum_{k=0}^{\infty} \sum_{n=0}^{\infty} p_k(w) A_{kn} p_n(\bar{z})$$

Then, given some holomorphic function $f(z)$ decomposed in terms of the polynomials, so that $f(z) = \sum_n a_n p_n(z)$, one has that

$$\begin{aligned} [\mathcal{A}f](w) &= \int \mathcal{A}(w, z) f(z) d\mu(z) \\ &= \sum_k \sum_n p_k(w) A_{kn} a_n \\ &= w \sum_n a_n p_n(w) \\ &= wf(w) \end{aligned}$$

That is, given a sequence (a_0, a_1, a_2, \dots) , the Hessenberg matrix acts as a right-shift, mapping it to the sequence $(0, a_0, a_1, \dots)$.

This is perhaps a bit silly, as one could instead just perform the same manipulation without the $f(z)$, by observing that, formally,

$$\mathcal{A}(w, z) = w \sum_{k=0}^{\infty} \sum_{n=0}^{\infty} p_k(w) p_n(\bar{z})$$

The above treatment is breezy and “formal”, paying no heed to summability, convergence or responding to any questions about what spaces the various vectors may live in. This is as appropriate, since the task here is to discover which spaces are the appropriate ones, when the Hessenberg matrix arises from the beta shift.

Notice that the word “operator” is a bit mis-used, here, as a vague synonym for “infinite-dimensional matrix”. Properly, the word “operator” should be reserved for an infinite-dimensional matrix acting on some given space, having general properties that are independent of the basis chosen for that space. So far, that might not be the case here: the infinite-dimensional matrices here might not be bounded operators; they might not even be continuous, viz. we have not ruled out the possibility that the space of interest is some Fréchet space or some more general topological vector space. It is well known that operators on such spaces can have “unexpected” discontinuities, unexpected in that they are not seen in ordinary Banach spaces.

At any rate, if polynomials obtained from the beta shift are orthogonal on some domain $D \subset \mathbb{C}$ that is the support of some measure $d\mu$, it is not at all clear what this measure might be. They are certainly not orthogonal on the unit disk, with uniform measure.

Notice also that the above treatment seems to be a special case of a more general principle: when an operator has a continuous spectrum, it can sometimes be interpreted as a right-shift. That is, given some arbitrary operator \mathcal{H} , then if one has that $\mathcal{H}f = \lambda f$ and λ takes arbitrary values $\lambda \in D \subset \mathbb{C}$, then \mathcal{H} can be taken to be a right-shift operator, provided that $f = f(\lambda)$ can be decomposed into a set of orthogonal polynomials in λ .

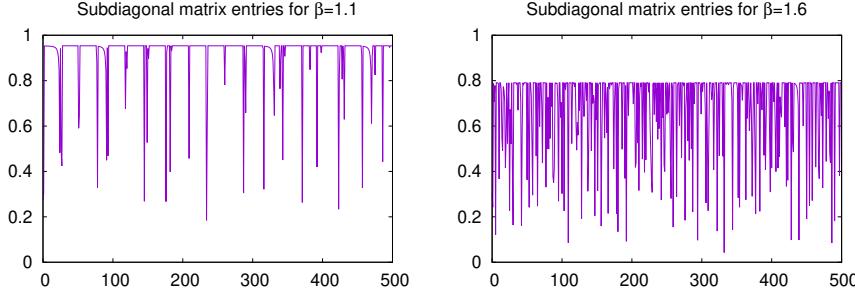

10.2 Beta Bergman Shift

The primary question for this section is whether the β -transform transfer operator, in the Hessenberg basis, can be considered to be a Bergman shift.

To obtain the orthogonal polynomial basis, one must satisfy the constraint that $A_{n+1,n} > 0$ for the matrix elements $A_{kn} = \langle k | \mathcal{L}_\beta | n \rangle$ of eqn 25. Numeric exploration indicates that this is indeed the case, with the sub-diagonal entries all positive (none are zero), and all tend to have the same value, with sporadic exceptions. These are shown in figure 36.

Can one find a domain on the complex plane that would have such Bergman polynomials? The references[44, 46] provide a technique for doing so, provided that the matrix is asymptotically Toeplitz. That is, if the diagonals of A_{ij} have nice limits, that $\lim_{n \rightarrow \infty} A_{n-k,n}$ exists for fixed k , then a Jordan arc bounding a domain on the complex plane can be found. The figure 36 indicates that this limit does not exist, in the strict sense: the values bounce away from an obvious limit point indefinitely. Exactly what

Figure 36: Sub-diagonal Entries

These charts show the sub-diagonal matrix entries $\langle n+1 | \mathcal{L}_\beta | n \rangle$ for the first $n < 500$. The left graph shows $\beta = 1.1$, the right shows $\beta = 1.6$; other values behave similarly. A scatterplot of the location of the spikes as a function of β does not reveal any structure. That is, except for small n , the location of a spike shows no smooth variation as β is varied smoothly. There does appear to be some structure for small n – some banded sequences – and so perhaps the correct statement is that the system is mixing, as n increases.

this implies is unclear. Perhaps it is possible to extend the results of [44, 46] to matrices that are where the diagonals merely have an accumulation point, as opposed to a well-defined limit?

Based on numeric exploration, it appears that the domain is the unit disk. That is, $A^T \vec{p} = z \vec{p}$ holds for $|z| \leq 1$.

10.3 Bergman Alternative

The Bergman polynomials of eqn 36 define an orthonormal basis for some region of the complex plane. For the square-integrable norm, this basis is the basis of a Hilbert space, and specifically, that of a reproducing kernel Hilbert space.

Yet, something funny happens on the unit disk. Let $p_m(z)$ be the polynomials, and for some sequence of coefficients $\{a_n\}$, consider a generic function

$$f(z) = \sum_{k=0}^{\infty} a_k p_k(z)$$

Consider the case where the $\{a_n\}$ are a right-eigenvector of the Hessenberg operator, that is, where

$$\sum_{m=0}^{\infty} A_{km} a_m = \lambda a_k$$

Substituting into the above, one has

$$f(z) = \sum_{k=0}^{\infty} \frac{1}{\lambda} \sum_{m=0}^{\infty} A_{km} a_m p_k(z) = \frac{z}{\lambda} \sum_{m=0}^{\infty} a_m p_m(z) = \frac{zf(z)}{\lambda}$$

There are two alternatives to solving this; either $f(z) = 0$ or $z = \lambda$. Since this is a reproducing kernel Hilbert space, then if $z = \lambda$ is part of the domain of the Bergman space, then one must conclude that $f(z) = 0$ everywhere. That is, right-eigenvalues of A correspond to functions $f(z)$ that are vanishing. To invent a new name, by analogy to the Fredholm alternative, perhaps this can be called the Bergman alternative.

Numerical exploration indicates that, for the matrix elements of eqn. 25, the function $f(z)$ vanishes inside the unit disk $|z| < 1$, and is undefined (infinite) outside of it.

10.4 Left Factorization

XXX TODO: somewhere just above, or maybe only below, I accidentally swapped left and right. Thus, almost everything that is written is correct, except that some of the transposes are in the wrong places. This needs review and correction.

Suppose one is given an (arbitrary) sequence of polynomials $(p_n(z))_{n=0}^\infty$, such that the order of p_n is n . Then each individual polynomial can be expanded as or $\beta > \varphi$,

$$p_n(z) = \sum_{k=0}^n p_{nk} z^k$$

This defines an infinite matrix $\mathcal{P} = [p_{nk}]$, provided that the coefficients are extended so that $p_{nk} = 0$ whenever $k > n$. This matrix is manifestly lower-triangular. Writing vectors $\vec{z} = (z^n)_{n=0}^\infty$ and $\vec{p} = (p_n(z))_{n=0}^\infty$ as before, the above is just the matrix equation

$$\vec{p} = \mathcal{P}\vec{z}$$

Consider now the case where the polynomials were constructed from some irreducible Hessenberg matrix A . The earlier observation that A^T is a shift, namely, that $A^T \vec{p} = z\vec{p}$ can now be written as

$$A^T \mathcal{P}\vec{z} = z\mathcal{P}\vec{z} = \mathcal{P}z\vec{z} = \mathcal{P}\mathcal{K}\vec{z}$$

In the above, the z without the vector notation is just a scalar, and thus commutes (trivially) with \mathcal{P} . Its eliminated by explicitly making use of the right-shift (Koopman) operator, which, in this basis, is

$$\mathcal{K} = \begin{bmatrix} 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & \ddots \\ 0 & 0 & 0 & 0 & \ddots \end{bmatrix}$$

Since \mathcal{P} is lower-triangular, it is invertible on the right, that is, the inverse \mathcal{P}^{-1} exists, and so one is left with

$$\mathcal{P}^{-1} A^T \mathcal{P} = \mathcal{K}$$

The irreducibility of A is important, here; non-zero entries on the sub-diagonal are required, else trouble ensues.

Rearranging, this provides an explicit decomposition of A into triangular matrices:

$$A^T = \mathcal{P} \mathcal{K} \mathcal{P}^{-1}$$

Taking the transpose, this gives

$$A = [\mathcal{P}^{-1}]^T \mathcal{K}^T \mathcal{P}^T$$

with \mathcal{P}^T and $[\mathcal{P}^{-1}]^T$ both being upper-triangular, and \mathcal{K}^T being the left-shift.

This system is solvable. Given some matrix A in Hessenberg form, the matrix elements of \mathcal{P} can be computed recursively, in a finite number of steps (i.e. in closed form), directly from 36. The explicit expression is

$$A_{n+1,n} p_{n+1,j} = p_{n,j-1} - \sum_{k=0}^n A_{kn} p_{kj}$$

The starting conditions are $p_{00} = 1$. To handle the $j = 0$ case in the above, set $p_{n,-1} = 0$.

Because \mathcal{P} is lower triangular, its inverse $\mathcal{P}^{-1} \equiv \mathcal{R} = [r_{kn}]$ can be obtained explicitly. Along the diagonal, one has $r_{nn} = 1/p_{nn}$ while the lower triangular form means $r_{kn} = 0$ for $k < n$. For the remaining entries $m < n$, one has

$$0 = \sum_{k=m}^n p_{nk} r_{km}$$

This can be solved in a finite number of iterations on

$$p_{nn} r_{nm} = - \sum_{k=m}^{n-1} p_{nk} r_{km}$$

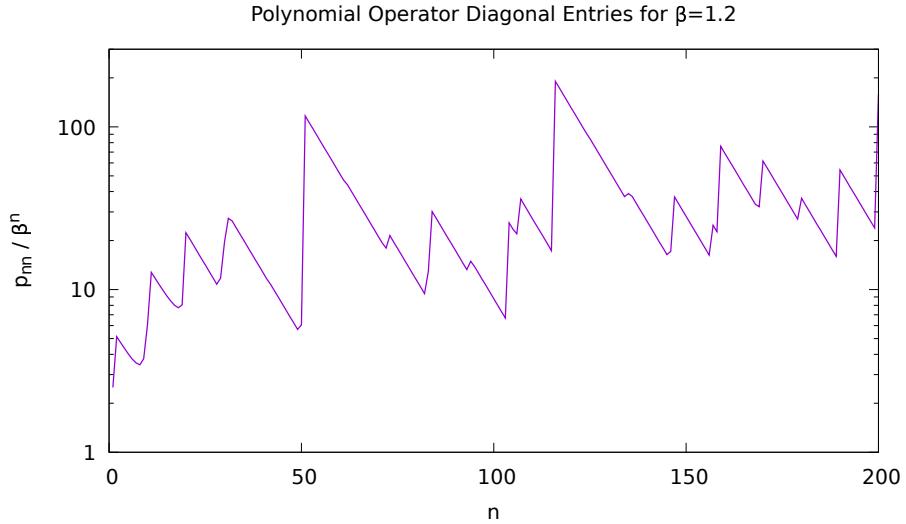

The above avoids questions of convergence, or any notion of the spaces on which the matrices or operators might act. The norm to be used for \vec{z} and \vec{p} is not specified. This is appropriate at this stage: it is the algebraic manipulations that are interesting, at this point, rather than the spaces on which the matrices/operators might act. One can invent several kinds of norms that might be applicable, but there is no particular reason to believe that \vec{p} might have a finite norm. Likewise, \mathcal{P} may not have a finite norm. For the case of the Hessenberg operator originating with the beta shift operator, it does not; the individual matrix elements p_{nm} increase without bound. That is, \mathcal{P} is an infinite matrix, but it is not clear that it is also an operator. If it is, it is certainly not a compact operator.

Some of the poor behavior can be brought under control by factoring $\mathcal{P} = \mathcal{D} \mathcal{N}$ with \mathcal{N} being unitriangular (all ones on the diagonal) and \mathcal{D} a diagonal matrix, with entries $[\mathcal{D}]_{nk} = p_{nn} \delta_{nk}$. With this factorization, one may then write

$$\mathcal{N}^{-1} A^T \mathcal{N} = \mathcal{D} \mathcal{K} \mathcal{D}^{-1}$$

so that $\mathcal{D} \mathcal{K} \mathcal{D}^{-1}$ has off-diagonal matrix entries $[\mathcal{D} \mathcal{K} \mathcal{D}^{-1}]_{nk} = \delta_{n+1,k} p_{nn} / p_{kk}$. This is a rescaling of the shift $[\mathcal{K}]_{nk} = \delta_{n+1,k}$. The scaling factor is exactly the sub-diagonal of the Hessenberg. That is, $p_{nn} / p_{n+1,n+1} = A_{n+1,n}$. The polynomials $\mathcal{N} \vec{z}$ are monic.

Figure 37: Polynomial Operator Diagonal Entries

This depicts the ratio p_{nn}/β^n of the diagonal matrix entries p_{nn} of the Bergman polynomial matrix operator \mathcal{P} for the beta shift with value $\beta = 1.2$. Other values of β are not dissimilar, although the spikes are pushed more closely together. The height of the spikes seems to be roughly the same, for all β . This is another way of visualizing the same information as in figure 36, as the ratio $p_{nn}/p_{n+1,n+1}$ is just given by the subdiagonal entries $A_{n+1,n}$ of the Hessenberg matrix. In particular, the straight edges correspond to usually-constant values on the subdiagonal.

10.5 Beta-transform factoids

An assortment of observations follow, for the case of the beta shift.

First, the matrix entries of \mathcal{P} grow in an unbounded fashion. It appears that $p_{nn} \sim \mathcal{O}(\beta^n)$; the ratio p_{nn}/β^n is depicted in figure 37.

Experimentation reveals two different regimes of behavior, depending on whether or not $\beta < \varphi = (1 + \sqrt{5})/2$ the Golden ratio. Exactly why there are two different regimes is unclear. Earlier sections motivated the reason for the appearance of the golden mean; why this shows up dramatically, as it does here, is unclear (to me).

One such result is that when $\beta < \varphi$, then the sum over columns of the Bergman operator vanishes. That is,

$$\sum_{k=0}^{\infty} p_{nk} = \delta_{n0}$$

This implies that every polynomial $p_n(z)$ has a zero at $z = 1$ (except for $p_0(z) = 1$) when $\beta < \varphi$.

10.6 Decaying Eigenfunctions

The matrix mechanics developed in the previous sections can be used to perform asymptotic expansions that rapidly converge to decaying eigenfunctions. This works most simply for the case of $\varphi < \beta$. TODO Write these down. TODO flesh out. Basically, write a vector \vec{w} with elements $w_n = \omega^n$ for $1 < |\omega|$ so that this is divergent. Then write the formal vector $\vec{d} = [\mathcal{P}^T]^{-1} \vec{w}$ which is formally divergent, but can be truncated in finite dimensions, and renormalized to be of unit length. Doing so provides an eigenfunction of A . The associated eigenvalue is 1 when $\beta < \varphi$ but is less than 1 when $\varphi < \beta$ (and in fact, the eigenvalue is exactly that depicted in figure 38). TODO graph some of these, explore more thoroughly, address the issues of formal divergence.

10.7 Moment Matrix

When the Hessenberg matrix is derived from measures on the complex plane, it takes the form of $\mathcal{M} = \mathcal{R}\mathcal{R}^T$ with $\mathcal{R} = \mathcal{P}^{-1}$, so that \mathcal{R} is the Cholesky decomposition of \mathcal{M} . This matrix is manifestly symmetric: $\mathcal{M} = \mathcal{M}^T$. Direct observation shows that it is almost positive-definite: one finds that $[\mathcal{M}]_{ij} > 0$ for all i, j except for $[\mathcal{M}]_{00} = 0$. This result can be strengthened: when $\beta < \varphi$, then $[\mathcal{M}]_{ij} > 1$ for all i, j except for $[\mathcal{M}]_{00} = 0$ and $[\mathcal{M}]_{0n} = [\mathcal{M}]_{n0} = 1$. But, for $\beta > \varphi$, one finds that $[\mathcal{M}]_{00} = 0$ and $[\mathcal{M}]_{01} = [\mathcal{M}]_{10} = [\mathcal{M}]_{11} = 1$, while all the rest obey $0 < [\mathcal{M}]_{ij} < 1$.

In the standard literature, \mathcal{M} is usually obtained from some moment matrix, viz, for the integral $\int \bar{z}^m z^n d\mu(z)$ for some measure $d\mu(z)$. Might that be the case here? Taking the time to numerically characterize the matrix, one finds that the ratio of successive rows (or columns as its symmetric) very quickly approaches a limit $\lim_{n \rightarrow \infty} [\mathcal{M}]_{nm} / [\mathcal{M}]_{n-1,m} = C(\beta)$ for some constant C that depends only on β but not on m . The limit $C(\beta)$ is graphed in figure 38.

For $\beta < \varphi$, it appears that $\lim_{n \rightarrow \infty} [\mathcal{M}]_{nm} = B(\beta)$ a constant, independent of m . This limiting value $B(\beta)$ is graphed in figure 39.

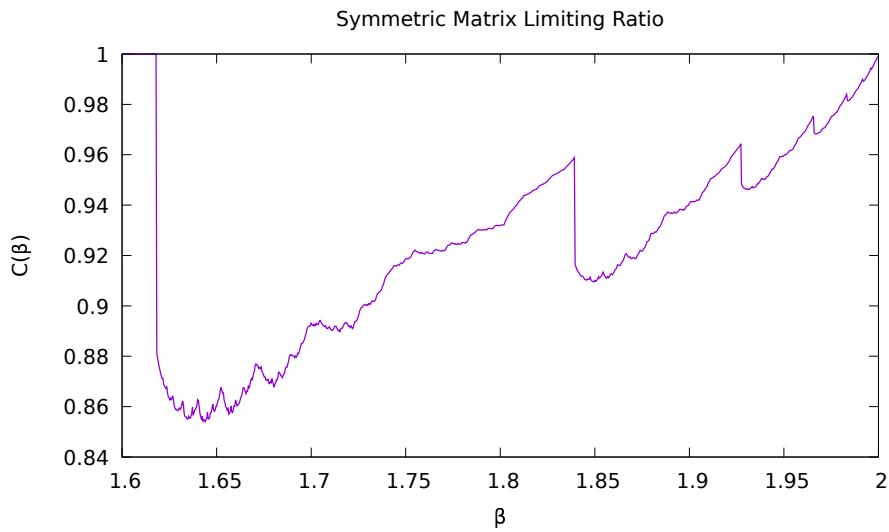

The asymptotic behavior of the matrix $[\mathcal{M}]_{ij}$ can be obtained as a moment matrix on point sources. A delta function located at $z = C$ for real C has the moments

$$\begin{aligned} C_{mn} &= \int \bar{z}^m z^n \delta(z - C) dz \\ &= \int r^m r^n \delta(r - C) r dr \int \delta(\theta) e^{-im\theta} e^{in\theta} d\theta \\ &= C^{m+n+1} \end{aligned}$$

Thus, for $\varphi < \beta$, the asymptotic behavior of $[\mathcal{M}]_{ij}$ is given by the distribution $A(\beta) \delta(z - C(\beta))$. What is $A(\beta)$? This is graphed in figure 40.

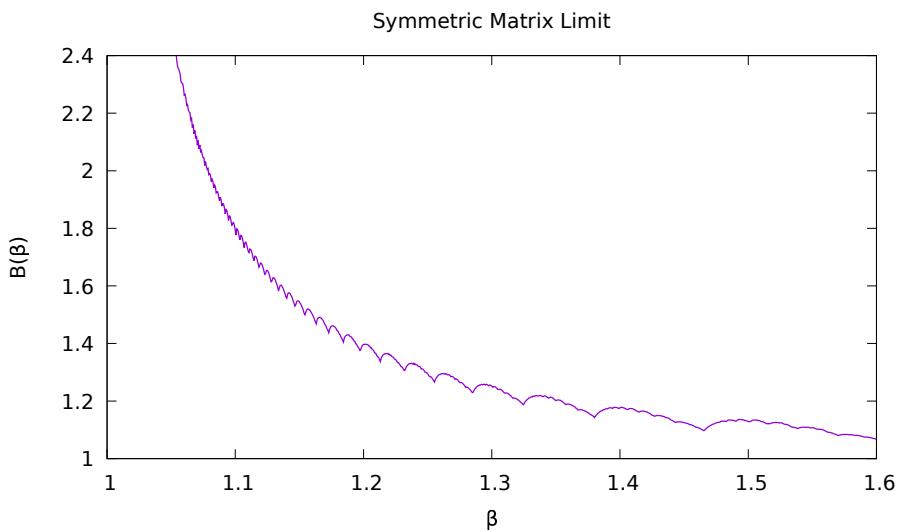

What about $\beta < \varphi$? A limiting constant distribution can be obtained from a deriva-

Figure 38: Symmetric Matrix Limit Ratio

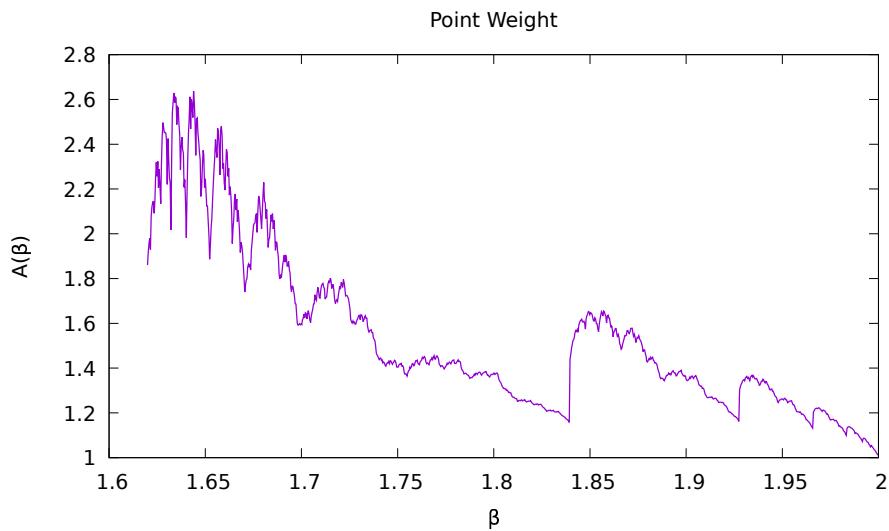

This figure shows the limit $C(\beta)$ defined in the text. Note that $C(\beta) = 1$ for $\beta < \varphi$. The jump is at about $\beta = 1.83928676\cdots$. Note this is one of the “troublesome midpoints” for the Hessenberg basis expansion, specifically for $T_\beta^3(\beta/2) = 0$ or $\beta/2$. This is one of the first “generalized golden means”, the positive real root of $\beta^3 - \beta^2 - \beta - 1 = 0$. The entire fractal structure presumably corresponds to higher iterates p that satisfy $T_\beta^p(\beta/2) = 0$.

Figure 39: Symmetric Matrix Limit

This figure shows the limit $B(\beta)$ defined in the text. The limit is approached fairly quickly for the larger values of β , but convergence proves difficult for $\beta \lesssim 1.1$. The overall shape is that of a hyperbola, but doesn't seem to actually be hyperbolic for either small or large β . The right-most nick in the curve appears to be at $\beta = 1.465571231876768\cdots$, another “generalized golden mean”, and the only real root of $\beta^3 - \beta^2 - 1 = 0$; equivalently, the root of $T_\beta^3(\beta/2) = 0$. The remaining nicks are presumably located at $T_\beta^p(\beta/2) = 0$ for higher iterates p .

Figure 40: Point Weight

This figure shows the value of $A(\beta)$ that gives the point weight of the moment matrix. That is, the asymptotic behavior of \mathcal{M} is given by $[\mathcal{M}]_{mn} \rightarrow \int z^m z^n \rho(z) dz$ with the measure given by a point mass $\rho(z) = A(\beta) \delta(z - C(\beta))$. Clearly, there is a strong resemblance to figure 38.

tive point mass located at $z = 1$. That is,

$$\begin{aligned} D_{mn} &= \int \bar{z}^m z^n \delta'(z-1) dz \\ &= \int r^m r^n \delta'(r-1) r dr \int \delta(\theta) e^{-im\theta} e^{in\theta} d\theta \\ &= 1 \end{aligned}$$

so that the asymptotic behavior of $[\mathcal{M}]_{ij}$ for $\beta < \varphi$ is given by the distribution $B(\beta) \delta'(z-1)$. The prime superscript here means derivative, viz, in colloquial language, $\delta'(z) = d\delta(z)/dz$.

11 The Jacobi Operator

Given a Borel measure on the real number line, one can find a sequence of polynomials that are orthonormal with respect to that measure. These polynomials $p_n(x)$ are coupled together by a three-term recurrence equation

$$xp_n(x) = a_{n+1} p_{n+1}(x) + b_n p_n(x) + a_n p_{n-1}(x)$$

with $p_0(x) = 1$ and $p_{-1}(x) = 0$. This recurrence relation can be taken to be an operator, known as the Jacobi operator \mathcal{J} , acting on vectors consisting of the polynomials $p(x) = \{p_n(x)\}$ so that

$$[\mathcal{J}p](x) = xp(x)$$

so that p is an eigenvector of \mathcal{J} with eigenvalue x . The two sequences of coefficients $\{a_n\}$ and $\{b_n\}$ form three diagonals of the operator, with $\{a_n\}$ running down the center, and $\{b_n\}$ the two diagonals on either side[43].

Given that the invariant measure for the β -transform, given by eqn 17 and visualized in figure 1 is a Borel measure, it seems reasonable to ask: what is the corresponding Jacobi operator? How can the sequence of polynomials be understood?

Szegő polynomials w.r.t. $d\mu$ are a set of orthogonal polynomials on the unit circle. Applying a Cayley transform gives the Schur functions, obeying a rational recurrence relation solvable via continued fractions. Hmmm.

And then there is Favard's theorem...

11.1 Moments

Construction of the polynomial sequences require moments. Since the invariant measures (and all of the eigenfunctions) are linear combinations of the Hessenberg basis functions, it suffices to compute the moments for these. Since the basis functions are piece-wise constant, and have an explicit expression given by eqn 24, the moments can also be given explicit expression:

$$\int_0^1 x^{n-1} \psi_p(x) dx = \frac{C_p}{n} \left[\frac{m_p^n - m_l^n}{m_p - m_l} - \frac{m_u^n - m_p^n}{m_u - m_p} \right]$$

with the midpoint m_p and the lower and upper midpoints $m_l < m_p < m_u$ defined just as before. Clearly, the moments rapidly get small as $n \rightarrow \infty$. Likewise, for fixed n , these also rapidly get small as $p \rightarrow \infty$.

12 The Multiplication Operator

The difficulties presented in the previous section suggests that studying the multiplication operator might be simpler. Multiplication by β is given by

$$M_\beta(x) = \beta x \quad (37)$$

The corresponding transfer operator is

$$[\mathcal{M}_\beta f](y) = \frac{1}{\beta} f\left(\frac{y}{\beta}\right)$$

The multiplication operator, superficially, in itself, is not terribly interesting; it simply rescales things. It does not generate fractals, at least, not if one confines oneself to real numbers and the canonical topology on the real-number line. If instead one works with the product topology on 2^ω , then the multiplication operator becomes rather complicated and difficult to analyze. In this sense, it is promising: it avoids the overt complexity of the logistic map, the tent map and the beta shift, yet still has a complicated behavior in the product topology. In particular, the multiplication of two numbers appear to involve chaotic dynamics of the carry bit.

12.1 Beta-shift, Revisited

The beta shift of eqn 4 takes a simple form when reinterpreted on bit-strings: it is the concatenation of multiplication, followed by a left-shift. Given a bit-string $(b_n) = 0.b_0b_1b_2\dots$ denote its left-shift by U given by

$$U(0.b_0b_1b_2\dots) = 0.b_1b_2\dots$$

which, for real numbers, corresponds to

$$U(x) = \begin{cases} 2x & \text{for } 0 \leq x < \frac{1}{2} \\ 2x - 1 & \text{for } \frac{1}{2} \leq x \leq 1 \end{cases}$$

which is none-other than the Bernoulli shift of eqn 1 with a change of notation. The beta shift is then

$$T_\beta(x) = M_\beta(U(x))$$

so that the iterated beta shift is an alternation between a left-shift and a multiplication. The act of discarding the most significant bit (the MSB) with each left-shift alters the dynamics of iterated multiplication.

This suggests that studying multiplication and the multiplication operator might provide fruitful insight into the beta shift.

12.2 Monomial Eigenfunctions

Some properties of the multiplication operator can be guessed at directly. Obviously, $f = \text{const.}$ is a decaying/growing eigenfunction, depending on whether $\beta > 1$ or not. That is, one should imagine $f = \text{const.}$ as a uniform distribution of dust; with each iteration, it is spread either farther apart ($\beta > 1$) or bunched closer together ($\beta < 1$).

Clearly, $f(x) = x^n$ is an eigenfunction, with eigenvalue $1/\beta^{n+1}$. If one considers multiplication only to operate on the positive real-number line, then n need not be an integer. In other words, the multiplication operator has a continuous spectrum in this situation.

If the domain of the operator is extended to functions on the non-negative real-number line, then n must be positive, as otherwise $f(0)$ is ill-defined. But if n is positive, then (for $\beta < 1$) the multiplication operator only has eigenvalues greater than one, which is not, in general, very desirable.

If the domain of the multiplication operator is extended to the entire real-number line, then n is forced to be an integer, in order to avoid issues due to multi-valued functions. Extending the domain to the complex plane leads us astray, and so we will not go there.

12.3 A Fractal Eigenfunction

The compressor function is also an eigenfunction. It was previously observed in eqn 14 that

$$\text{cpr}_\beta\left(\frac{x}{\beta}\right) = \frac{1}{2}\text{cpr}_\beta(x)$$

whenever $1 < \beta \leq 2$ and $0 \leq x < 1$ and so, cpr_β is potentially be an eigenfunction of \mathcal{M}_β with eigenvalue $1/2\beta$, provided that it is extended to arguments $1 < x$. This can be done as follows. Define the extended function, valid for $0 \leq x < \infty$ and for $1 < \beta \leq 2$ as

$$\text{ecpr}_\beta(x) = \begin{cases} \text{cpr}_\beta(x) & \text{if } 0 \leq 2x < \beta \\ 2\text{cpr}_\beta\left(\frac{x}{\beta}\right) & \text{if } \beta \leq 2x < \beta^2 \\ 4\text{cpr}_\beta\left(\frac{x}{\beta^2}\right) & \text{if } \beta^2 \leq 2x < \beta^3 \\ 2^n\text{cpr}_\beta\left(\frac{x}{\beta^n}\right) & \text{if } \beta^n \leq 2x < \beta^{n+1} \end{cases}$$

The extension is performed simply by treating the self-similarity as a recurrence relation, which can be iterated to move the argument into a region where the original definition was sufficient. In essence, one applies a right-shift operator to reduce the argument. Since the multiplication operator is odd about $x = 0$, one can trivially extend this to negative x by defining $\text{ecpr}_\beta(-x) = -\text{ecpr}_\beta(x)$.

Note that the original $\text{cpr}_\beta(x)$ also had a translation symmetry: the upper half was equal to the lower half. This translation symmetry has been lost, since after all, multiplication does not preserve translation.

The ecpr function is not square integrable; it does not have an L_p -norm for any p ; and this is no surprise, as it's hard to imagine how it could be otherwise, for a function to be self-similar under scaling.

12.4 A Generic log-periodic Eigenfunction

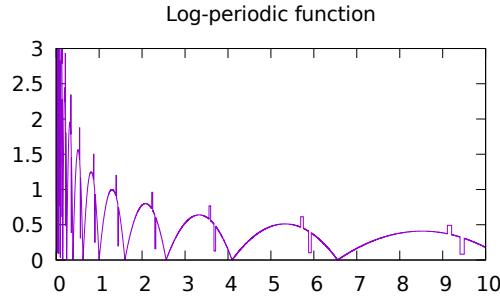

Inspired by the above, it's clear how to build a generic eigenfunction. Let $g(x)$ be some arbitrary function, defined on the interval $1 \leq x < \beta$ (given some fixed $1 < \beta$). Define its extension as

$$g'_w(x) = w^n g\left(\frac{x}{\beta^n}\right) \text{ if } \beta^n \leq x < \beta^{n+1}$$

This has, by construction, the self-similarity relation $g'_w(\beta x) = w g'_w(x)$ and so is an eigenfunction with eigenvalue w/β :

$$[\mathcal{M}_\beta g'_w] = \frac{w}{\beta} g'_w$$

This function is merely log-periodic; it's not fractal. Perhaps it's silly to illustrate this; it should be obvious, but just in case it's not, the figure below shows such a function, for $\beta = 1.6$ and $w = 0.8$. It is an eigenfunction of $\mathcal{M}_{1.6}$ with eigenvalue of $1/2$.

There doesn't seem to be anything particularly interesting with this particular game. There's a simple explanation for this: The multiplication operator is generating a free monoid in one generator (the iteration itself), whereas fractals require at least two generators of self-symmetry. The (usually) free interaction of multiple generators is what forces the fractal to appear.

Note that the cpr_β function constructed above is a special case of this: It's self-similar, but the property that made it interesting, as a fractal, was erased in the construction. As before, note that $g'_w(x^n)$ is an eigenfunction with eigenvalue $1/\beta w^n$ (for integer n).

12.5 Haar Basis Matrix Elements

The Haar basis matrix elements for the beta shift proved to be a bit unwieldy and not terribly useful. The corresponding matrix elements for the multiplication operator have the same general essence, but are slightly simpler and shorter to write down. In all other respects, they still have the same tractability issues.

The multiplication operator \mathcal{M}_β has matrix elements in the standard Haar basis:

$$\begin{aligned}\langle mi | \mathcal{M}_\beta | nj \rangle &= \int_{-\infty}^{\infty} h_{mi}(x) [\mathcal{M}_\beta h_{nj}](x) dx \\ &= \frac{2^{(m+n)/2}}{\beta} \int_{-\infty}^{\infty} h(2^m x - i) h\left(\frac{2^n x}{\beta} - j\right) dx\end{aligned}$$

Instead of confining oneself to the unit interval, here it is convenient to consider the entire real-number line, and thus that is the range of the integral. Likewise, i and j can be any integers, positive or negative. As before, matrix elements vanish unless

$$\left[\frac{i}{2^m}, \frac{i+1}{2^m} \right] \cap \left[\frac{\beta j}{2^n}, \frac{\beta(j+1)}{2^n} \right] \neq \emptyset$$

This holds in three cases: where one of the intervals contains an edge transition (left, middle or right) of the other interval, without also containing the other two.

12.6 The Shift and Add algorithm

One can model the multiplication of real numbers with a number of different algorithms applied to bit strings. One of the simplest such algorithms is the shift-and-add algorithm, described here. Its just elementary-school long-form multiplication, applied to the binary expansions of the numbers.

There's a point worth laboring on: a bit string representing a real number is not the same thing as the real number. There are more bit-strings than there are real numbers. Most famously, the two bit strings $0.0111\dots$ and $0.1000\dots$ are two obviously distinct bit-strings, but they represent the same real number: one-half. All real numbers of the form $j/2^n$ (the “dyadic rationals”) will always have dual representations; all other real numbers have a single, unique representation. These correspond to the “gaps” in the Cantor set, or, equivalently, neighboring infinite branches in the finite binary tree. Bit-strings are not real numbers. They're just a usable model of them. The usability is somewhat limited; its OK for working with individual points, but fails miserably for the topologies: the canonical topology on the reals is sharply different than the product topology on 2^ω .

The goal is to compute the product Kx with $0 \leq K \leq 1$ and $0 \leq x \leq 1$ so that the product is $0 \leq Kx \leq 1$. Both K and x are represented by their binary expansions. Let the binary expansions be

$$x = 0.b_0 b_1 b_2 \dots = \sum_{n=0}^{\infty} b_n 2^{-n-1}$$

and

$$K = 0.c_0 c_1 c_2 \dots = \sum_{n=0}^{\infty} c_n 2^{-n-1}$$

where the b_n and c_n are either 0 or 1, always.

Define $s_0 = 0$ and s_{n+1} to be the non-negative integer

$$s_{n+1} = b_n c_0 + b_{n-1} c_1 + \cdots + b_0 c_n = \sum_{k=0}^n b_k c_{n-k} \quad (38)$$

Note that $0 \leq s_n \leq n$. It is useful to visualize this in terms of the elementary school shifted tabular form:

$$\begin{array}{ccccccc} 0 & c_0 b_0 & c_0 b_1 & c_0 b_2 & c_0 b_3 & \cdots \\ & c_1 b_0 & c_1 b_1 & c_1 b_2 & c_1 b_3 & \cdots \\ & c_2 b_0 & c_2 b_1 & c_2 b_2 & c_2 b_3 & \cdots \\ + & & & c_3 b_0 & c_3 b_1 & \cdots \\ \hline s_0 & s_1 & s_2 & s_3 & s_4 & \cdots \end{array}$$

This makes clear the shift-and-add form. The value of each individual s_n can be visualized as a stack of blocks. For the special case of $K = 0.111\cdots = 1$ one has that $s_{n+1} = \sum_{k=0}^n b_k$, that is, it is simply the total number of one-bits in the first n locations.

The final step is to reduce the sum series s_n to a bit-string. This is accomplished recursively, by performing a carry operation:

$$d_n = s_n + \left\lfloor \frac{d_{n+1}}{2} \right\rfloor \quad (39)$$

where $\lfloor d \rfloor = d \bmod 1$ denotes the floor of d (the integer part of d). The desired bit sequence is then

$$a_n = d_n \bmod 2 \quad (40)$$

Equivalently, a_n is the remainder, the part of d_n that was not propagated to the next location. Explicitly, is is $a_n = d_n - 2 \lfloor d_n/2 \rfloor$. The carry-sum propagation can be imagined as a kind of bulldozer, razing the towers d_n until they are one block high, pushing the razed bits off to the next location. The resulting sequence (a_n) is then the bit-string for the product Kx . That is,

$$Kx = 0.a_0 a_1 a_2 \cdots = \sum_{n=0}^{\infty} a_n 2^{-n-1}$$

The problem with this algorithm is that the relation 39 for the d_n is infinitely recursive, and in general is not guaranteed to terminate. One has to start at $n = \infty$ and move backwards from there. There are two plausible scenarios for computing the a_n in practice. One is to search the n until one finds that spot where $\lfloor d_{N+1}/2 \rfloor = 0$; one can then obtain the a_n for all $n < N$ without issue. The problem here is to find such an N .

The other way to compute is to observe that the iteration is convergent. The recursion 39 only depends on a finite and fixed number of bits “behind it”, roughly equal to $\log_2 n$ bits that come after this. As noted earlier, $0 \leq s_n \leq n$ and likewise, $0 \leq d_n \leq 2n + 1$. To write down d_n , one needs at most $C = 1 + \lfloor \log_2(2n+1) \rfloor$ bits. This implies that a given d_n can only perturb at most $C - 1$ bits downstream of it. That

is, d_{n-C+1} depends on d_n but d_{n-C} does not. Thus, in order to correctly compute all bits a_k for $0 \leq k \leq n - C$, it is sufficient to set d_n to some arbitrary value (less than $2n + 2$) and then iterate (using the correct values for s_k when $k < n$). At the end, discard all d_k and a_k for $n - C < k$, as they are incorrect.

12.7 Tree-view

Points:

- 1) adding one bit is like shifting the tree over sideways.
- 2) multiplying by one bit is like shifting the tree down-left.
- 3) adding a number to itself is like shifting tree up (since its just $2x$)

13 Simplified Models of Multiplication

The shift-and-add algorithm is obviously rather complex; can it be replaced by something simpler? The particular question to ask is how much of the chaotic dynamics of the beta shift is due to the propagation of the carry bit, and how much of it is due to other parts of the algorithm? Specifically, the addition of two numbers, which requires a carry bit, can be replaced by a bit-wise XOR of their bit strings: this generates “almost” the same results as addition, when the number of 1-bits in the strings are sparse, but are wrong when 1-bits appear in the same location: the XOR discards the carry bits. Thus, a simplified model of multiplication would be the shift-and-XOR model: it proceeds the same way as shift-and-add, but replaces addition with XOR. What does this look like, and how does the equivalent of the beta shift behave under this operation?

13.1 Shift-and-XOR

The shift-and-XOR algorithm must like the shift-and-add algorithm, except that it drops the carry bits. Starting from the same spot, let $0 \leq K \leq 1$ and $0 \leq x \leq 1$ and represent both by their binary expansions:

$$x = 0.b_0b_1b_2\cdots = \sum_{n=0}^{\infty} b_n 2^{-n-1}$$

and

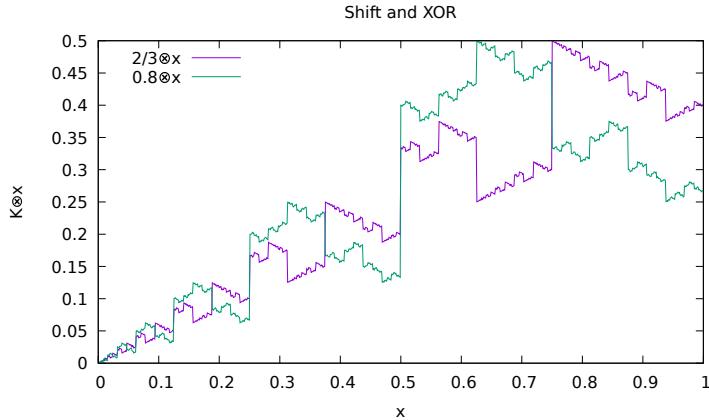

$$K = 0.c_0c_1c_2\cdots = \sum_{n=0}^{\infty} c_n 2^{-n-1}$$

where the b_n and c_n are either 0 or 1.

Define $s_0 = 0$ and s_{n+1} to be the result of XOR-ing instead of adding the bits.

$$s_{n+1} = b_n c_0 \oplus b_{n-1} c_1 \oplus \cdots \oplus b_0 c_n = \bigoplus_{k=0}^n b_k c_{n-k}$$

Figure 41: Shift and XOR Algorithm

This figure shows two functions, $(2/3) \otimes x$ and $(4/5) \otimes x$ as a function of x .

Here, the oplus symbol \oplus denotes the XOR operation. Note that each s_n is either zero or one. Reconstructing a real number from this, one defines

$$K \otimes x = 0.s_0 s_1 s_2 \dots$$

where the otimes symbol \otimes is pressed into service to indicate the shift-and-XOR product. Note that it is symmetric: $K \otimes x = x \otimes K$ and so behaves at least a bit like ordinary multiplication. Its is not distributive over ordinary addition: $(a+b) \otimes x \neq a \otimes x + b \otimes x$ but it is distributive over XOR: $(a \oplus b) \otimes x = (a \otimes x) \oplus (b \otimes x)$. It is illustrated in figure 41.

The range of the shift-and-XOR operation is fundamentally different from multiplication. First, because the carry bit is dropped, one has that $s_0 = 0$ always, and so that $K \otimes x \leq 1/2$ always, even when both $K \rightarrow 1$ and $x \rightarrow 1$. Next, for any value of $1/2 < K \leq 1$, the range of $K \otimes x$ runs over the entire interval $[0, 1/2]$ as x runs over the interval $[0, 1]$. The measure is not compressed (other than by a factor of 2), as there is in ordinary multiplication. That is, if $S \subset [0, 1]$ is a measurable subset of the unit interval, with measure $\mu(S)$, then one has $\mu(K \otimes S) = \mu(S)/2$. There are several ways to prove this. One formal approach is to consider the correspondence between the natural measure on the reals, and the measure of cylinder sets on the product topology. That is, the Cantor space $\{0, 1\}^\omega$ is endowed with a natural topology, the product topology. The open sets of this topology are called ‘‘cylinder sets’’. Their measure is uniformly distributed over unit interval, precisely because the Bernoulli shift is ergodic: the one implies the other.

Indeed, the shift-and-XOR algorithm can be best thought of as a formula for shuffling the bit-strings around, without actually altering them: re-ordering them, not changing them. The intuitive key to this is to observe that subtracting x from 1 just re-orders the unit interval, top to bottom, and that this is the same as flipping all zero bits to one, and v.v. That is, $1 - x = x \oplus 0.111\dots$

Another way to see this shuffling is to note that $a \oplus a = 0$ and that $0 \oplus x = x$. Thus, for a fixed value of a , the string x and the string $a \oplus x$ are paired together, in a unique way, so that either can be gotten from the other. The function $a \oplus [0, 1] \rightarrow [0, 1]$ sending $x \mapsto a \oplus x$ is an exchange of these unique pairings of strings. It is not just a bijection, it is an involution. If the strings are given their natural lexicographic sort order, the mapping $x \mapsto a \oplus x$ is just a certain kind of shuffle of the sort order; it neither adds new strings, nor deletes any, nor changes their number. The function is one-to-one and onto. The multiply-and-XOR algorithm is just a repeated sequence of XOR's:

$$K \otimes x = \left(\frac{c_0 x}{2} \right) \oplus \left(\frac{c_1 x}{4} \right) \oplus \left(\frac{c_2 x}{8} \right) \oplus \dots$$

and so $K \otimes x$ is nothing more than a reshuffling of strings (along with a right-shift equal to the number of leading zero-bits in the binary expansion of K ; the right-shift commutes with the measure on the product topology.) Thus, $K \otimes x$ preserves the measure on the unit interval (up to a factor of 2^{-n} due to the above-mentioned right-shift). That is, for $1/2 < K \leq 1$, this discussion shows that $\mu(K \otimes S) = \mu(S)/2$.

13.2 Self-similarity

There are several self-similarity properties of the shift-XOR worth noting. It behaves very much like a classic dyadic fractal. Thus, one has that

$$K \otimes \left(\frac{x}{2} \right) = \frac{1}{2} (K \otimes x) = \frac{1}{2} K \otimes x$$

In addition... TODO: illustrate the other symmetry.

13.3 Similarity Transformations

The shift-and-XOR algorithm acts as a permutation on bit-strings. As a result, the XOR-analogs of the beta shift and the tent map become uniformly ergodic, behaving exactly as the Bernoulli shift. The Frobenius-Perron solution to these is just the uniform distribution, which is featureless. All of the structure visible in figures 2 and 3 is entirely due to the dynamics of the carry bit. Effectively, the carry-bit algorithm alters the uniform distribution of the Bernoulli shift (equivalently, the uniform distribution associated with the natural measure on Cantor space.)

Define the XOR-analog of the beta shift as

$$c_\beta(x) = \begin{cases} 2\beta \otimes x & \text{for } 0 \leq x < \frac{1}{2} \\ 2\beta \otimes (x - \frac{1}{2}) & \text{for } \frac{1}{2} \leq x < 1 \end{cases}$$

The factor of 2 makes up for the fact that shift-XOR effectively drops the top bit; thus the goal is to map each half of the unit interval into the entire interval $[0, 1]$.

Given a fixed β , define $\boxtimes_\beta : [0, 1] \rightarrow [0, 1]$ as

$$\boxtimes_\beta(x) = \beta \otimes x$$

As observed previously, \boxtimes_β is an automorphism of the unit interval, and more: it is a permutation on Cantor space. Let $b(x)$ be the Bernoulli shift of eqn 1; then one has that $c_\beta = \boxtimes_\beta \circ b$. Taken together, this implies that the ergodic properties of iterating on c_β follow directly from the ergodic properties of the Bernoulli shift; a shuffle, any shuffle on the Cantor set should not alter these ergodic properties.

TODO: similarity transforms on the transfer operator... and the non-alteration of the eigenspectrum, even as the eigenfunctions are altered.

13.4 Multiplication on the Cantor Space

The previous set of results indicates that all of the structure in the bifurcation diagrams of 2 and 3 is entirely due to the dynamics of the propagation of the carry sum. To explore this, the notation needs to be improved on.

The beta shift can be decomposed into multiple distinct stages. First, there is a conversion from the unit interval to the Cantor space; this was defined at the very start, but now we need a less awkward notation for it. Let

$$\begin{array}{ccc} \pi : 2^\omega & \rightarrow & [0, 1] \\ 0.b_0b_1b_2\cdots & \mapsto & x \end{array}$$

be the projection from the Cantor space to the real-number unit interval, given by eqn 2. Note that it is a surjection: dyadic rationals (rationals of the form $m/2^n$) correspond to two distinct bit strings. For example, $1/2$ can be represented as both $0.1000\cdots$ and as $0.0111\cdots$. Cantor space covers the unit interval. Write the inverse mapping as

$$\begin{array}{ccc} \pi^{-1} : [0, 1] & \rightarrow & 2^\omega \\ x & \mapsto & 0.b_0b_1b_2\cdots \end{array}$$

As a function, it is injective but not surjective. It is usually convenient to ignore this, and to pretend that both π and π^{-1} are bijections, even though they are not. This rarely leads to practical difficulties, as long as one stays conceptually tidy. Better yet, just perform all work on the Cantor space, and project to the unit interval only when needed.

Next, turn to multiplication. This has three parts. First, the summation of the carry bits:

$$\begin{array}{ccc} S_\beta : 2^\omega & \rightarrow & \mathbb{N}^\omega \\ 0.b_0b_1b_2\cdots & \mapsto & (s_0, s_1, s_2, \dots) \end{array}$$

where the summation is given by eqn 38. Here, \mathbb{N}^ω is Baire space, the space of all infinite-length sequences of non-negative integers. In number theory, this would be called the space of arithmetic functions. The second part of multiplication is the propagation of the carry bits. Denote this as

$$\begin{array}{ccc} C : \mathbb{N}^\omega & \rightarrow & \mathbb{N}^\omega \\ (s_0, s_1, s_2, \dots) & \mapsto & (d_0, d_1, d_2, \dots) \end{array}$$

which is defined in eqn 39. Finally, one extracts the remainder, after propagation:

$$\begin{array}{ccc} A : \mathbb{N}^\omega & \rightarrow & 2^\omega \\ (d_0, d_1, d_2, \dots) & \mapsto & (a_0, a_1, a_2, \dots) \end{array}$$

which is given by eqn 40. Of the three parts into which we've decomposed multiplication, only the first part is parameterized by K . Thus, multiplication, on Cantor space, can be written as $M_\beta = A \circ C \circ S_\beta$. The shift-and-XOR algorithm omits the propagation of the carry sum. On Cantor space, it is just $\boxtimes_\beta = A \circ S_\beta$: the XOR is just modulo-2 of the carry sum.

To obtain multiplication on the real-number unit interval, we need merely to re-project from Cantor space to the reals. Thus, multiplication, given in eqn 37, decomposes into

$$M_\beta = \pi \circ A \circ C \circ S_\beta \circ \pi^{-1}$$

The beta shift of eqn 4 is then

$$T_\beta = \pi \circ A \circ C \circ S_\beta \circ \pi^{-1} \circ b$$

where b is the Bernoulli shift. To simplify notation, it is convenient to go ahead and provide a symbol for the shift operator:

$$\begin{array}{ccc} B : 2^\omega & \rightarrow & 2^\omega \\ (b_0, b_1, b_2, \dots) & \mapsto & (b_1, b_2, \dots) \end{array}$$

so that $b = \pi \circ B \circ \pi^{-1}$. The corresponding beta shift on the Cantor space is

$$B_\beta = A \circ C \circ S_\beta \circ B$$

which eliminates the pesky projection π . It should be clear that S_β is an injection, the propagation operation C and the remainder A are both surjections.

As noted, the shift-and-XOR algorithm can be written as $\boxtimes_\beta = A \circ S_\beta$; the step where the carry bits are propagated is dropped. The XOR-version of the beta shift is

$$c_\beta = \boxtimes_\beta \circ B = A \circ S_\beta \circ B$$

Thus, in this new notation, it reaffirms that B is the true source of ergodicity, and that $A \circ S_\beta$ being a permutation does not alter the basic ergodic property of B . All of the structure in the bifurcation diagrams can be blamed on the propagation operator C .

13.5 Propagation games

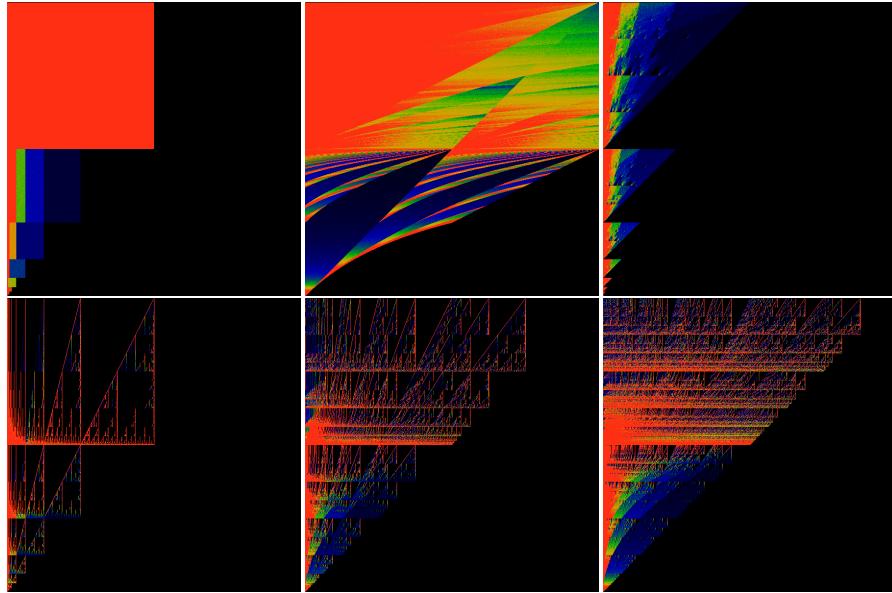

Pinning the “blame” of complex dynamical structure on the propagation of the carry bits seems to be an open invitation to replace the propagation operator C by just about anything, to see what happens. Figure 42 illustrates some of the things that can happen.

Reviewing the images there makes it clear that although fiddling with the carry bit fundamentally alters point trajectories, it completely fails to open any doors that would provide insight into the structure of the transfer operator. The pictures are pretty, but appear to be meaningless.

14 Sci-fi day-dreaming

This section provides two day-dreams inspired by this material. They are just that: daydreams. If you don't like fictional daydreaming, you won't like the material here. Sorry about that.

Figure 42: Carry-bit propagation

Two triptychs of different carry-bit behaviors. Define $F : \mathbb{N}^\omega \rightarrow \mathbb{N}^\omega$ by $F = f \times f \times f \times \dots$ and then iterate on $A \circ C \circ F \circ S_\beta \circ B$. For $f(n) = n$ one obtains, of course, the standard beta shift of figure 2. The top-left image shows $f(n) = n \bmod 2$, which is the same as iterating on the shift-XOR function c_β . Here, β runs from 0 at the bottom, to 2 at the top; x runs from 0 to 1, left to right. The uniform red square simply indicates that the iteration is completely independent of β when $1 < \beta \leq 2$: it is fully uniform and ergodic in the same way that the Bernoulli shift is. The top-middle image shows $f(n) = n + 1$, that is, pretending that there is one carry bit too many. The top-right shows $f(n) = \max(0, n - 1)$, that is, having one carry-bit too few.

The bottom three shows a progression of $f(n) = \max(n, 1)$, $f(n) = \max(n, 2)$ and $f(n) = \max(n, 3)$, allowing more and more carry bits to propagate. In the limit, this becomes figure 2 once again. Except for the top-left image, the rest seem pointlessly goofy.

14.1 Limits to computation

There are many limits to computation. One limit is the speed of light. In current generation CPU chips, clock rates in the vicinity of 3 gigahertz = 3×10^9 cycles per second. By comparison, the speed of light in a vacuum is about 3×10^8 meters per second. Dividing, one finds that light can travel about $3 \times 10^8 / 3 \times 10^9 = 10^{-1}$ meters, or about four inches: a bit bigger than the actual physical dimensions of a chip (typically around half-an-inch on a side), but not by much. Of course, the speed of light in a metal conductor is lower – about half the speed in a vacuum. And transistors are small – more than twenty-thousand times smaller. So, measured in terms of the size of the transistor, the speed of light is about ten or twenty transistor-widths per clock-cycle. So, OK, it's still fast, at that length scale. But not really all that fast. The point here is that the speed of light is a potential limit to the speed of computation, and it is not all that far away.

In this setting, one can imagine the situation where the speed of propagating the carry bit during multiplication becomes a limiting factor. The above work hints at a somewhat mind-boggling idea: can multiplication be effectively parallelized by working with transfer operators instead? That is, the multiplication of two numbers corresponds to point-wise particle dynamics: a discrete particle following a chaotic path through a complex numerical computation. By contrast, the transfer operator describes how a distribution propagates through a computation: it effectively performs “an infinite number” of multiplications at the same time, in parallel. That is, rather than asking how single values propagate, one could, and perhaps should, ask how distributions propagate – parallelize multiplication (for example) to an “infinite” degree. It is this rather ridiculous idea that suggests that the above explorations are not purely abstract, but have a potentially practical application. As I suggested – it's a bit of science-fiction day-dreaming at this point. But it does hint at an alternate model of computation.

Variants of this model have already been explored, for decades. For example, Crutchfeld defined “geometric state machines” as generalizations of finite state machines, where, instead of having a finite matrix (a “transition matrix”) act on a finite vector (the “state vector”), one instead considers operators acting on homogeneous spaces – that is, applying a sequence of such operators on homogeneous space. The most famous and celebrated such space would be the \mathbb{CP}^n – complex projective space, with the operators that act on it being the unitary ones: $U(n)$ – such a system defining the n -qubit quantum state machine. Distributions on \mathbb{CP}^n are mixed states – and the idea of quantum computing is to evolve such states through a set of operations.

Note that ALL quantum computing can be understood to be nothing more than a Crutchfeld machine. For whatever reason, this is almost never stated outright. This is unfortunate, since the Crutchfeld machine is quite easy to understand, whereas “quantum computing” seems to be mired in mystery, at least for the uninitiated.

The point here is that computation, by means of the time-like evolution of distributional densities, is already being explored, but in a rather different context than the one explored here. Here, it seems like we are bowled over by the complexities of a seemingly much simpler system.

14.2 Wave function collapse

There is also a different, bizarrely hypothetical way in which all of this apparatus could manifest itself. Currently, in order to avoid the rather severe issues associated with the concept of quantum-mechanical wave-function collapse, the (vast?) majority of practicing physicists believe in the many-worlds hypothesis. Clearly, this belief is entirely correct for microscopic systems, isolated from the usual thermodynamic hustle and bustle (chlorophyll, rhodopsin and the magnetically sensitive cryptochromes notwithstanding). But it seems to fly in the face of daily experience, where we are aware of just one reality. One of my favorite hypotheses is that this is the result of the (rapid) decay of macroscopic quantum states down to a probability of zero. The mechanism is presumably that of decaying subshift measures. Penrose argues that this has something to do with gravity; but we can go one better: the natural setting for shift spaces are hyperbolic spaces, as that is where there is enough room to “fit everything” in a uniform way consistent with a metric. Curiously, the world we live in – Minkowski space, is hyperbolic. This suggests that the Many Worlds interpretation is exactly right, as long as one truly is in Minkowski space, but that gravitation, which essentially bends or distorts it, squeezes down the room available for multiple quantum states, effectively forcing the collapse in this way.

Put another way: the standard treatment for quantum field theory is the Feynman functional integral; it can be viewed as an integral over all possible paths that a “particle” might take. The daydream is to equate a specific path with the idea of point-dynamics in an iterated function. As long as one considers only points, and their movement, one can be completely unaware of either the invariant measure, or of the decaying eigenstates of the shift operator. In a standard QFT textbook, all equations appear microscopically time-reversible. There’s almost no idea of a measure, except for the $\exp -i\hbar S$ in the Feynman integral. The incorporation of gravity into this is famously difficult. The daydream here is that gravity manifests itself as eigenfunctions that live off of the shell of unitary evolution.

There is some practical hope of bringing this daydream to fruition: the theory of subshifts has seen dramatic advances over the last few decades, getting increasingly abstract, and gaining a firm footing in very general settings: viz not just in metric spaces, but even in more general topological vector spaces, and specifically in stereotype spaces, where most of the devices used in analysis can be exercised in reasonably safe manner. The point here is that most of QFT can be formulated using these more-or-less conventional tools and notations. The trick is to locate and extract those parts that renormalize to zero, not unlike some of the formally divergent sums explored above, which can none-the-less be regulated and made to give reasonable answers. Or at least, that’s the daydream. Clearly, got far to go before it can be reality.

15 Topological Push-Forward

The transfer operator is most generally and correctly defined as an operator acting on the topology of a space, and specifically, as the push-forward of the (uniform) measure by the iterated function. That is, given any open set belonging to the topology, the

transfer operator assigns a different open set of the topology: it is a map of sets to sets. For iterated maps on the unit interval, it is essentially a map of cylinder sets, the open sets of the product topology. The shift-XOR experiment shows that the ergodic properties arise from the Bernoulli shift, and that all other properties, commonly called “chaotic”, are really the side effect of something else, entirely: the internal structure of the transfer operator. Fiddling with the carry-bits cannot reveal this structure; instead, they just define other, pointlessly goofy iterated functions. Point trajectories fail to reveal the internal structure of the transfer operator, and at best point in a misleading direction. To understand the transfer operator, it must be tackled for what it is: one must look at how intervals are mapped to intervals, and what sort of symmetries can be discovered in this mapping. (I’ve given one sketch of a proof of the transfer operator as a push-forward in this reference:[28]. There are surely better, more accessible and more formal and mathematically refined presentations; if you, reader, know of such, please drop me a line.)

The action of the transfer operator on the sets belonging to the topology of the reals reveals several distinct kinds of actions. The topology on the reals can be generated from a basis consisting of connected sets. The transfer operator will map some connected sets to other connected sets, simply moving them around, shrinking or expanding them. In other cases, a connected set will be split into two disjoint parts. For maps that are continuous, there must be regions that have fixed-points and period-doubling routes to chaos: these correspond to the (countable number of) “trouble spots” illustrated in section 8.

It seems reasonable to argue that each of these different kinds of moves creates a distinct group (or monoid) of transformations: in a certain sense, those transforms that do not change the connectivity, nor do any folding, are all similar to one-another. It should be possible to write down exactly which sets belong to this type, and then give explicit transformation properties between them. Likewise, those connected sets which are split in two are all similar. It seems like there should be a prototype: a generic split, followed by some re-arrangement of the two parts. How can this classification be written in an insightful, useful way?

I believe that there has been a sufficient number of advances in the theory of subshifts so that the above vague sketch can be presented in a fairly concrete way. Unfortunately, most of the relevant material remains rather arcane and abstract, lacking in direct accessibility to casual students. I am not currently aware of any adequate yet accessible treatment.

16 Conclusion

What, exactly, is the point of analytic mathematics, especially in the computational age? Can’t one just get a fast computer, iterate on the logistic map, and find out everything there is to find? Well, of course, yes, and no: these questions can be taken as either silly or as deeply philosophical, and it is worth the effort to understand them and address them properly.

First, let’s dispose of some obvious mis-perceptions. If one carefully scrutinizes figure 1, one will find signs of a slight unevenness in the horizontal bars. These are

numerical artifacts due to statistical under-sampling: they smooth out and fade away with additional sampling of the iterated equations. There is a way to obtain this same figure, far more rapidly, and without this particular form of numerical noise: one can instead iterate on equation 18. This suggests one philosophical answer: the goal of mathematics is to find faster ways of computing things; to discover better algorithms.

A unifying theme between this, and the other text that I have written on fractal issues, is that they are all explorations of the structure of the Cantor set, the structure of the space of infinite sequences of symbols, and the structure of the continuum. That is, we know the continuum in two different ways: one way is by means of the natural topology on the real number line; the other is the product topology on the space of binary strings. The former is suggested by the physical universe that we actually live in: a continuum with spatial extents. The latter is suggested by the notion of time and repetition: the making of choices naturally leads to a tree structure; tree structures necessarily embed in hyperbolic spaces; the Minkowski space that we live in is hyperbolic, and this is why, every day, as time passes on, we get to make new choices precisely because the amount of room for possibilities is ever-increasing as time flows forward.

The idea of analytic combinatorics takes on a whole new meaning in the computational age. Historically, the ability to provide an “exact solution” in the form of an analytic series has been highly prized; the ultimate achievement in many cases. Being able to express a solution in terms of the addition and multiplication of real numbers is very comforting. Every school student eventually comes to feel that arithmetic on the real numbers is very natural and normal. It’s more than that: Cartesian space is smooth and uniform, and all of differential geometry and topology are founded on notions of smoothness.

The inner workings of computers expose (or hide!) a different truth. The most efficient algorithm for computing $\sin(x)$ is not to sum the analytic series. Arbitrary precision numerical libraries open the rift further: neither addition nor multiplication are simple or easy. Both operations have a variety of different algorithms that have different run-times, different amounts of memory usage. In the effort to minimize space and time usage, some of these algorithms have grown quite complex. The root cause of the complexity is bewildering: it is the use of the binary digit expansion to represent a real number. Computers use the Cantor space $\{0, 1\}^\omega$ or at least a subset thereof, under the covers.

Different representations of the real numbers potentially offer different algorithms and performance profiles. One could represent reals by rationals, but then several other issues arise. One is that the rationals are not evenly distributed across the real number line: rationals with small denominators cluster about in a fractal fashion. This is easily exhibited by considering continued fractions. As a result, one promptly gets stuck in a quagmire of trying to understand what a “uniform distribution” should be. Binary expansions are more “obviously” uniform. A more basic issue is that, if working with rationals, one must somehow accomplish the addition or multiplication of two integers. To accomplish this, one has to represent the integers as sequences of bits, which only takes us back to where we started. There is no computational oracle that automatically knows the sum or product of integers: it has to be computed.

Compare this situation to that of iterated functions and fractals. At first impression, these seem pathological in almost every respect: differentiable nowhere, unbounded

and non-uniform: somehow they feel like the quintessential opposite of the analytic series, of the smoothness of Cartesian space, of the smoothness of addition and multiplication. The place where these two worlds come together is that both are attempts to approach countable infinity, and both are attempts to harness the first uncountable infinity. The real number number is an infinite string of binary digits. The analytic series is an infinite sum. The iterated function is recursively infinite. The historic labor of finding “exact solutions” to problems can perhaps be better views as the discovery of correspondances between finite structures (“the problem to be solved”) and infinite structures (“the solution”).

The situation here is more easily illustrated in a different domain. The hypergeometric series was presented and studied by Gauss; then Kummer, Pfaff and Euler observed various identities yoking together different series. By the 1950’s, thousands of relations were known, along with some algorithms that can enumerate infinite series of relations. The current situation is that there is no known algorithm that can enumerate all such relations; there is no systematic way to classify them. There is an interplay between infinite series and algorithmic relationships between them. Stated a different way: hypergeometric series have a class of self-similarities, and the identities relating them are expressions of that self-similarity. What is that class of self-similarities? For the hypergeometric series, it remains unknown.

For Cantor space, that place where we represent real numbers, the situation is much better. The Cantor space itself has the structure of an infinite binary tree; the tree and its subtrees are obviously self-similar; the class of similarities is described by the dyadic monoid. The dyadic monoid embeds naturally into the modular group; this in turn is a gateway to vast tracts of modern mathematics. The recursive aspects, the shadow that the Cantor space seems to leave behind everywhere appears to be “explained” by Ornstein theory.

Yet, the picture remains incomplete. The β -transform provides a simple, silly model for multiplying two real numbers together: β and x . The “extra complication” of taking mod 1 after multiplication just reveals how complex multiplication really is. After all, mod 1 is just the subtraction of 1; how hard can that be? Moving in one direction: the fastest, most efficient-possible algorithm for multiplying two numbers is not known. Moving in another direction, the simple iterated maps, shown in figures 2, 3 and 4 are obviously not only self-similar, but also are surely topologically conjugate to one-another, and in all cases are presumably described by the dyadic monoid; likewise the Mandelbrot set and its exterior. Yet the details remain obscure.

The meta-question is: what is the correct framework by which one can best understand the interplay between symmetries, infinite series, infinite recursion and algorithms? Until modern times, mathematical practice has reified addition and multiplication into oracular operations that magically obtain “the right answer”. Modern computers have put a lie to this: the theory of numerical methods has made clear that addition and multiplication are necessarily algorithmic operations performed on finite truncations of infinite series. What other algorithms are hiding nearby, and what is their relationship to analytic series?

17 Bibliography

The references below provide a bibliography that attempts to touch on all the different ways in which the beta transform and beta expansions have been studied. Search engines exist to help you find the things you don't know, and want to find out more about.
